Glossary

Cognitive style A pattern of thinking with which an individual processes information that is independent of context.

Growth mindset Learners are capable of adapting their learning and are not fixed in their ability to learn.

Learning difference The diversity exhibited by learners when engaged with material, processing the context, and understanding the information.

Learning disability A legal qualifier to ensure a student has access to educational resources to meet learning accommodations.

Learning style An individual's preference for perceiving information that interacts with the environmental context.

Meshing hypothesis Matching the individual's unique learning style with the mode of instruction or curriculum will achieve optimal success.

Overview of Learning Differences

Human creativity is a complex and diverse attribute. Learning differences, which is an umbrella term that includes both learning disabilities and learning styles, as well as the method with which individuals perceive, process, and remember information contributes to this diversity.

Learning Differences

Learning disabilities and learning differences are often used interchangeably in the field of education and psychological sciences but there are important distinctions between the two. In the United States, a learning "disability" is a legal qualifier in the Individuals with Disabilities Education Act ("IDEA") and Section 504 of the Rehabilitation Act. These are federal mandates that protect the rights of students between the ages of three and 21, and provide mandated special education services. To receive these resources, a student must exhibit one or more of the thirteen qualifying learning disabilities which include autism, blindness, deafness, emotional disturbance, hearing impairment, intellectual disability, multiple disabilities, orthopedic impairment, other health impairment, specific learning disability, speech/language impairment, traumatic brain injury, or visual impairment. The learning disability must affect the student's academic performance leading to the need for specialized instruction from an Individual Instruction Plan (IEP). Similarly, the civil rights law Section 504, provides accommodations for students with disabilities that impact learning. The recent edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM) provides diagnostic criteria for Learning Disability which includes dyslexia, dyscalculia, and difficulties with reading fluency or comprehension, and problem-solving. Learning disabilities are fairly prevalent, impacting about 5% of American students in a variety of areas including reading, math, writing, speech, and executive functioning terms.

By contrast, a learning difference is not a diagnostic term and does not usually appear in neuropsychological/psycho-educational evaluation nor on an Individual Education Plan. Instead it is an umbrella term for several subcategories that impact learning. These subcategories typically include learning disabilities and learning styles. Much of the early attention on the connection between learning differences and creativity has been generated from historical evidence. While learning differences can impact academic performance and daily functioning, the result is not always detrimental.

Anecdotally, the positive impact of learning differences on creativity and problem solving has been demonstrated by reviewing the achievements and inventions of several creative geniuses who achieved greatness in a variety of fields such as art, music, physics,

and writing. Many of these renowned experts exhibited high levels of creativity, which is defined as “the interaction among aptitude, process, and environment by which an individual or group produces a perceptible product that is both novel and useful as defined within a social context” (Plucker et al., 2004, p. 21). Successful creativity and problem solving requires understanding the task, drawing on knowledge from long term memory, divergent thinking, synthesizing, and evaluating the ideas. Creativity therefore, is not immune to being influenced by learning disabilities.

There are many examples of successful individuals who had or may have had learning disabilities. For example, singer, songwriter, and co-founder of the Beatles in the 1960s, John Lennon excelled in music and songwriting but also had a history of academic struggles, poor concentration, and inventive spelling, which many believe was attributed to undiagnosed dyslexia.

Einstein, who greatly excelled at visual and spatial creativity, is believed by many to have had Asperger’s syndrome and dyscalculia. Both of these learning disabilities may have created a hyper focus in visual and systematic areas in mathematics and physics thus allowing him to visualize complex mathematical patterns differently than his peers.

Temple Grandin, originally diagnosed as brain damaged and subsequently with sensory processing disorder, is now believed to be on the autism spectrum and greatly excelled in science and photo-realistic visual thinking. She went on to become the first inventor to design a calming device to reduce sensory overload for those with autism and was the first scientist to report that cattle are prone to sensory overload. Grandin developed a series of new techniques to promote the humane treatment of cattle.

While parallels can be drawn between learning differences and creativity retroactively among creative geniuses, they are problematic for two main reasons. First, any association drawn lacks scientific control and, in any observation of posthumous historical figures, misinformation, assumptions, or even observer biases may lead to inaccurate conclusions. Second, the focus on creativity is limited to highly successful, renowned experts. This is not surprising as much empirical research on learning ability and creativity has primarily addressed above average ability and gifted learners. For that reason, attention to the diverse impact of learning differences is an important area of work as it focuses on the learner, the environment, and the context to determine the optimal environment needed to promote success in learning, problem solving, and creativity.

However, it may not be a coincidence that many creative geniuses exhibited dyslexia, dyscalculia, autism, or Asperger’s Syndrome as these learning differences are among the most prevalent learning disabilities. Dyslexia is perhaps the most studied learning disability in its relation to creativity and problem solving. It impacts an individual’s ability to decode phonemes, read fluently, and comprehend text passages.

Much of the research on the impact of dyslexia and creativity has focused on adult populations using divergent thinking tests such as the Alternative Uses Task. This assessment prompts the test taker to list as many ideas for common household objects such as a paperclip or newspaper. The responses are then scored for several qualifiers such as fluency (the number of ideas), flexibility (the different types of ideas provided), originality (responses that are statistically rare), and elaboration or expressiveness (the amount of detail in the response). Because these assessments tend to be verbal in nature and often timed, any learning difference that inversely impacts memory, writing, or executive function would likely negatively impact subsequent performance.

Additional assessments that include figural components, can avoid the verbal influence by providing an alternative measure of creativity that requires the individual to complete a series of incomplete figures or generate ideas to an abstract image, or improve a toy design. Similarly, both Holland’s Creativity Activity and Accomplishment Checklist and the Creative Behavior Questionnaire provides a list of verbal creative activities such as “I have had a piece of literature published”, and nonverbal activities, such as “I have made jewelry”. The respondent then reports the frequency of engaging in those behaviors.

The research findings on the impact of dyslexia on creativity are what would be expected. Those with dyslexia may exhibit reduced verbal creativity but there is no reduction in figural creativity. Children who exhibit signs of dyslexia not only may have impairments in verbal tasks such as reading and writing but may also struggle with mathematics. Dyscalculia, which is the difficulty in understanding and manipulating numbers, math formulas, and interpretation of visual data in graphs, exhibits a high degree of comorbidity with dyslexia. While there is little research on the sole impact of dyscalculia on creativity, it is generally believed that because dyscalculia impairs number retrieval and estimation of basic calculations, advanced calculations required in the field of mathematics and physics may be immune. This is the reason some children who struggle to succeed in everyday classrooms go on to astound onlookers with their creative ability in those fields.

Another prevalent learning disability, autism, is a neurodevelopmental disorder in which an individual exhibits impaired social interaction, limited communication, and has a restriction of activities that are often repetitive in nature. While a diverse spectrum of characteristics exists, a subcategory, generally viewed as high-functioning, is Asperger’s Syndrome (AS). Similar to characteristics found with autism, those with AS may exhibit a preference for restriction and repetition of an all-absorbing interest in a specific topic. While this drive for systematization may reduce imagination it can be a valuable attribute in creative problem solving by producing more detailed concrete and realistic ideas.

Though research on learning disabilities tends to focus on impairments or weaknesses, research on learning differences tends to focus on the benefit of cognitive diversity in thinking and problem solving that may be different from typical individuals.

Learning Styles

While not a diagnosable learning disability, learning styles, a subcategory of learning differences, refers to the preference of material to provide optimal learning for an individual.

Learning styles are typically viewed as an individual's predisposition for perceiving and processing information in specific ways. Generally viewed as a consistent trait, it is believed that once a learning style is identified, educators can present material conducive to the learner's style in order to facilitate encoding, recall, problem solving, and creativity. While learning styles interact with the content and material, they vary from person to person. In contrast, cognitive style refers to a pattern of thinking that is independent from the content.

Historically, the initial research and test development for learning styles was conducted in the 1980s by David Kolb who speculated that students exhibit different and consistent preferences for learning activities. Developing the first assessment, the Learning Style Inventory (LSI), he theorized four types of learning styles within the experiential learning process. These four styles fall into a quadrant that contains two dimensions. The first dimension focuses on thinking such that individuals exhibit a preference of either active thinking or reflective thinking. Those who prefer to be active will initiate their assignment by writing, calculating, or designing as the project unfolds. In contrast, those who are reflective prefer to have the entire assignment and an outline of the project before generating their response. The second dimension refers to the information. Individuals either prefer to have concrete information or abstract information. Those who prefer concrete information want to process each chunk of information in meaningful, individual pieces, whereby those who are abstract view the assignment in global terms. These two dimensions then create four quadrants: *accommodating style* (concrete and active), *diverging style* (concrete and reflective), *converging style* (abstract and active), and *assimilating style* (abstract and reflective).

Those with **accommodating** style prefer organized rules and step-by-step instruction with less attention on theory as typically found in business organization and managerial fields. Their form of creativity would be most pronounced in a design aspect of planning and organizing that includes gathering background information and outlining goals. They excel in generating a unique method of organization. Those with **diverging** style tend to excel on brainstorming activities and imaginative. Their form of creativity would be evidenced in generating many unique and original ideas as they prefer learning with interpersonal communication and group projects typically found in journalism, group discussion, competitions, and role play sessions. In contrast, those with **converging** style prefer convergent thinking and are solution driven. They prefer learning routine and well defined problems that have clear expectations that yield a single correct answer typically found in gathering statistical information and generating models. Their creativity would be witnessed in adapting formulas or generating new rules in the field. Those with **assimilating** style tend to excel in synthesizing information. They prefer ill structured problems that have unclear methods, unknown rules, and require insight to reach solutions typically found in the sciences or engaging in creative problem solving. Their creativity is most likely found in altering the field by driving it into a new direction.

While Kolb focused on individual learning preferences and suggested that teachers should develop lesson plans to suit individual learning styles, he pointed out that the optimal learning curriculum, would contain all four quadrants (See Fig. 1) whereby an individual generates a plan (accommodating), gathers information (diverging), integrates the information (converging), and reflects on the solution to then make adjustments as needed (assimilating). This curriculum is witnessed in many contemporary paradigms such as brainstorming and problem based learning).

Perhaps one of the most popular learning styles is the Visual, Auditory, and Kinesthetic (VAK) learning style model proposed by Dunn and Dunn in 1970s (Dunn and Dunn, 1972).

Praised for its simplicity, the VAK, proposed that, while learner's may exhibit all three types of learning style, only one of the three types of preferred learning is dominant.

Figure 1 Interaction of the four components of Kolb's learning styles model.

Those with **visual** style prefer seeing visually with information presented via illustrations, charts, diagrams, and formulas. Visual learners excel when instructions and directions are written rather than spoken and are able to recall visual information (such as faces after an introduction) at higher rates. They often create mental images, tend to think in pictures, enjoy doodling and color coding, and are more perceptive to changes in the visual field. Their creativity is most likely demonstrated in writing, drawing, and visualizing complex patterns of data as well as three-dimensional tasks such as architectural and design. To promote creativity, presentation of and interaction with visual information that includes design features (colored coded graphs or computer design programs) are recommended.

Those with **auditory** style prefer hearing information that is presented via lectures and discussions. Auditory learners excel when instructions and directions are read aloud rather than written and are able to recall spoken information (such as names after an introduction) at higher rates. They may whisper aloud while reading and tend to enjoy the phonemic patterns found in rhymes and iambic pentameters. Their creativity is most likely demonstrated in poetry, musical performances, debates, group discussions, or presenting speeches. To promote creativity, interactive discussion sessions and environments that permit reasonable noise levels are encouraged.

Those with **kinesthetic** style prefer information that is tactile from dance, movements, or touching and excel when they are fully engaged in the task and instructions are physically shown. They are able to recall proprioceptive information (such as gymnastic routines or dance moves often after only one demonstration) at higher rates. They often put their bodies into the work to create physical routines. Their creativity is most likely demonstrated in movement such as hand-on activities as well as four-dimensional tasks such as dance choreography, drama presentations, martial arts, athletics, and science projects. To promote creativity, props and hands-on interactive activities as well as an environment that allows movement is encouraged.

Updates to this model include the VARK (Fleming and Mills, 1992) which maintain the visual, auditory, and kinesthetic, but includes the addition of reading/writing. Those with **reading/writing** style prefer interacting with text via book and video. Reading/writing learners excel when instructions and directions are printed and are able to process and remember information that they actively read. Their creativity is most likely demonstrated in word play, poetry, and writing.

Embedding the VARK in education and curriculum planning, proponents of this learning style propose that age related changes interact with learning style such that young children in preschool and early elementary school tend to be kinesthetic (touching objects and benefitting from hands-on learning that includes movement). As they continue into later grades elementary school (i.e., age 8) they transition to become visual learners and benefit from printed material and illustrations. By middle school (i.e. age 12) they may become auditory learners as they generate mental frameworks from spoken instruction.

Another model proposed by Felder and Silverman (1988) delineated learning styles into four domains: **perception** (the interaction of the learner with the information in either sensory or intuitive), **input**, (preference for external information visual or verbal) **processing** (either active or reflection), and **understanding** (either sequential or global). Each component within the Felder-Silverman learning style model (FSLSM) corresponds to recommended teaching styles such that *perception* requires teachers to provide content in either concrete or abstract. This would foster creative expression that is either literal, and follows a prescribed pattern, or theoretical and innovative, and follows, as of yet, unknown paths. *Input* requires presentations in either visual or verbal forms that correspond to creativity expression in printed visual forms such as drawing or diagrams or verbal forms through poetry recitals or speeches. *Processing* requires students to be active or reflective in their participation. Creative expression would result in a generation of novel ideas or products or a reflection and connection of ideas to previously established concepts. And lastly, *understanding* requires the teachers to provide information in a manner is either sequential or simultaneous. Creativity is expressed through a sequential nature may be a mathematical formulas while creativity expressed through a simultaneous form may be pattern recognition. Felder and Silverman's Index of Learning Styles (ILS) was subsequently designed and has been popular in both education and technology design to promote learning, problem solving, and goal setting. Presenting information simultaneously rather than sequentially generally improves creative performance.

In line with the theory that there are multiple learning styles, Gardner's developed his well-known multiple intelligences during the 1980s. Outlining eight distinct intelligences provides insight into how student process and interact with information to generate a creative idea. Similar to the verbal style in VAK, those with **linguistic** intelligence excel by interacting with world with through writing or speech. They prefer to take written notes of spoken information and thinking often think in textual words rather than images. Their creativity would excel in synthesizing written information, writing, and creating poetry or writing stories. Similar to the visual style in VAK, those with **visual-spatial** intelligence are skilled at processing and interacting with information that is presented visually such as formulas and diagrams. Their creativity is most pronounced in visual art, pattern recognition, and they are apt at mental rotation tasks. Those with **logical-mathematical** intelligence excel in activities that require scientific reasoning and calculations often found in conducting scientific experiments. Their creativity can be witnessed in solving analytical problem or generating novel experiments to test theories. Similar to the kinesthetic style in VAK, those with **bodily-kinesthetic intelligence** perform better with hands on activities and express their creativity through coordination and movement such as dance, acting, and athletics. Those with **musical** intelligence are tuned into sounds in their environments and excel in musical composition and recognizing pitch and tone. Those with **interpersonal** intelligence have heightened cognitive and affective empathy and are capable of understanding other people's emotions. They excel in character development in writing and in group dynamics such as communications and diffusing intergroup conflict. Those with **intrapersonal** intelligence excel in self-reflection and identifying their own emotions. They perform best through writing, introspection, and reflection.

Connecting Learning Styles to Creativity

Creativity and problem solving is witnessed in many domains including the obvious fields such as art and music but also the less obvious ones such as STEM (Science, Technology, Engineering, and Mathematics). Therefore, there are strong parallels between learning styles and promoting problem solving and creativity in many fields. Employing Kolb's theory, creative expression is fostered by promoting multiple active thinking processes such as divergent and convergent thinking. In contrast, in both the VAK and VARK models, the learning styles result in creative products such as poems or dance.

Synthesizing both the process and the product while drawing heavily from the fields of engineering and science, Felder-Silverman's learning style model promotes creativity through following math formulas to generating new math theories. Gardner's (1983) theory promotes several subfields of creativity and creative expression from dance to imagery (See Fig. 2).

Controversies

Aligning teaching styles to learning styles is a popular approach. For example, some individuals considered to be visual learners may benefit from having information presented visually and may exhibit a reduction in performance if information is presented mainly in an auditory manner (Kolb, 1984). In fact, it is because of this conventional wisdom that learners exhibit predispositions for various learning styles, that many current classroom practices provide students with a variety of verbal, auditory, and visual information. It is thought that by providing all three media modalities will enhance learning in a group setting by accommodating those various types of learners (i.e., provide text, auditory, and visual information to address all possible types of VAK learning styles). Furthermore, one might theorize that a student's learning style (preference for textual information over visual information or vice versa) would predict individual differences in performance. For example, if students are visual learners they should perform better when information is presented via graphs and diagrams, whereas if students are auditory learners, they should perform better when information is read aloud.

An extension of the older scaffolding hypothesis and "the problem of the match", the Meshing Hypothesis or belief that educational curriculum, when matched to a learner's corresponding learning styles will promote success is so ingrained in classrooms that most accept it as fact. However, much of the theories addressing learning styles come from observations in the school setting rather than scientific research experiments. As a result, when tested with controlled empirical experiments, learning styles does not hold up to scrutiny. While learners often have clear preference for information, those preferences have little, if any, impact on their actual learning. A meta-analysis of studies assessing learning style suggests that student's achievement levels may not benefit from matching the style of an instructional technique to their preferred learning style (Stahl, 1999) and further research fails to support the idea that learning styles promotes actual learning. Perhaps most critical was Coffield's et al. (2004) analysis of 13 popular learning styles to review the reliability and validity of each model. They found poor reliability and validity in the measurement as well as limited benefits of employing any learning style on subsequent academic performance. This same lack of benefit has been established for creative performance.

Author	Learning Style	Concept	Creative expression example
Kolb (1984)	Learning Style	accommodating style	concept mapping
		diverging style	brainstorming
		converging style	convergent thinking
		assimilating style	synthesis
Dunn & Dunn (1972)	VAK	visual	graphic design and art
		auditory	rap music, poetry recital
		kinesthetic	dance
Fleming & Mills (1992)	VARK*	reading/writing	creative writing, journalism
Felder & Silverman (1988)	Felder-Silverman learning style model (FSLSM)	perception	instruction and developing theories
		input	flow charts or speeches
		processing	recipes and innovation
		understanding	math formula and pattern recognition
Gardner (1983)	Multiple Intelligence	linguistic	creative writing, journalism
		visual-spatial	imagery and mental rotation
		logical-mathematical	analytical problem solving
		bodily-kinesthetic intelligence	dance, athletics
		musical	musical performance or composition
		interpersonal	communication with others
		intrapersonal	self-reflection

*includes VAK

Figure 2 Overview of Popular Learning Styles.

Based on these conclusions, it has been recommended to discontinue the use of the Meshing Hypothesis and not embed learning style models in the classroom. Yet, even when armed with this knowledge, 15 years later, learning style theories still remain the most popular myth among both teachers and the public.

There are several concerns about the continued use of the meshing hypothesis to design educational curriculum. An obvious concern is the continued use of non-scientific based practices. A second concern is the knowledge that creativity is best fostered by addressing the *domain specific learning* rather than an individual's learning style. With the knowledge that creative problem solving is domain specific, educators should generate curriculum based on content, not learner's preference. However, most content is rarely conducive to one modality, so a thoughtful combination of multiple modalities is recommended. A third concern is that if students are aware of their own learning style, it can promote a fixed mindset whereby they believe they cannot improve an area outside their learning style based on restricted ability. This can greatly impact student motivation and success in several academic topics.

Moving Beyond the Myths

Given a further understanding of learning differences, learning disabilities, and learning styles, a shift in understanding is needed to develop optimal environments to foster creativity and problem solving.

Often creativity is reserved for gifted education classroom, when instead it should be incorporated in all academic environments and for all ability levels. A diagnosis of dyslexia, dyscalculia, or autism can bring unique challenges to educational environment. By focusing on limitations and fixed traits that are characteristic of learning differences an individual may inadvertently be discouraged from reaching his or her potential. The belief that creative ability is a fixed trait and cannot be increased, while popularly believed, has been repeatedly established as a myth. Instead it is consistently found that creativity can be taught in a variety of areas. Promoting a growth mindset may help avoid these academic myths thus enabling learners to develop their creativity in multiple areas. Encouraging a growth mindset, rather than fixed mindset, fosters creative ability and results in greater success.

Unfortunately, accommodating learning differences to design lesson plans that correspond to students' learning style is a popular paradigm. But research fails to support its validity.

To overcome pseudoscience, it is recommended that evidence-based approaches to instructional design that are appropriate to the content be employed. Educators should target their resources and time on combining multi-modalities of instruction to strengthen the student's comprehension of the content. Targeting the content of the material and encouraging a growth mindset, can help students become more effective in solving problems, making decisions, generating ideas, and becoming more creative.

Introducing the Link Between Creativity and Reasoning

Where do the best ideas come from? By what process or processes does an individual or team arrive at an elegant or original solution to a previously intractable problem? The potential answers to these questions, and the research paradigms that may be used to draw those possible conclusions, are clearly relevant to creative work and creativity research, because the production of ideas that are simultaneously original and meaningful lies at the heart of creativity (Runco and Jaeger, 2012). However, another and perhaps equally fruitful perspective on the investigation of these general research questions lies in the tradition of cognitive psychological research on reasoning. For example, the process of producing a highly creative idea may be described as a special case of reasoning or problem-solving, where the solution is both effective and also original. On the other hand, the reasoning process, when it is especially successful, may produce just such an effective and novel solution to a given problem. In this way, it seems clear that the individual mental functions, and probably also group discourse processes, that the creativity literature recognizes as relevant to the production of creative ideas may also be legitimately described as reasoning. How then, can one differentiate the two constructs and processes in order to inform further research, theoretical discussion, or even educational intervention? In this entry, evidence from throughout the psychological literature on creativity and cognition is marshalled to elucidate the similarities and differences between the creative process and the more logical process of reasoning.

Differentiating Reasoning Processes From Creative Processes

Traditionally within the creativity literature, the principal way in which reasoning or problem-solving processes are differentiated from more quintessentially creative thought is through the convergent and divergent thinking distinction. In this categorization, which is most often attributed to Guilford (1967), convergent thinking processes are those mental functions that allow an individual or group to *converge* upon an optimal solution to a given problem, regardless of whether or not that solution is original or novel. For example, an engineering team may effectively converge on an optimal solution to a mechanical design problem by drawing an analogy between the problem at hand and a previous problem they encountered, allowing them to effectively solve their problem without necessarily thinking originally.

In contrast, divergent thinking processes allow individuals or groups to produce a number of ideas that *diverge* in key ways from the initial problem or a culturally normative solution. For example, the same engineering team, when faced with a mechanical design issue, may choose to posit a number of divergent solutions to their problem, that are not structurally related to previous solutions they utilized. If one or more of these divergent solutions is feasible and effective, it would be a creative solution. However, there would certainly be no guarantee that the creative solution is more optimal, in terms of economic or engineering constraints, than the more prototypically convergent solution. In this section, a number of logical reasoning processes (deductive, inductive, and relational reasoning) as forms of convergent thinking will be described as well as four key components of divergent thinking (fluency, originality, flexibility, and elaboration).

Reasoning as Convergent Thinking

From the perspective of creativity research, reasoning processes can largely be characterized within the general category of convergent thinking, because they allow individuals or groups to target a correct or optimal solution to a problem. Such reasoning process are clearly relevant to creativity because the forwarding of a meaningful or effective solution (whether or not it is original) must require convergence in order to ensure that the solution is effective for the problem context.

Deductive reasoning. One classic form of reasoning, studied by philosophers for thousands of years, is deductive reasoning. Deductive reasoning is a highly formalized mental process that is based on premises about the environment that must be true in order for the deductive reasoning process to be effective. If the premises associated with the deduction are true, and the deductive reasoning process proceeds without errors, then the deductive conclusions must necessarily be true.

For example, one classic form of deductive reasoning—referred to as the syllogism—typically includes premises about the categorization of objects or people. Such as: *All reptiles are cold-blooded; All snakes are reptiles; Therefore, all snakes are cold-blooded.* In this example, if the two premises about reptiles and snakes are absolutely true, then the conclusion about snakes being cold-blooded must be absolutely true as well. For this reason, deductive reasoning has traditionally been privileged in Western philosophy as the most quintessential and most trustworthy form of reasoning. Some philosophers of science, most notably Popper (1959), have argued that all valid scientific reasoning should proceed deductively. This tradition in science is referred to as the hypothetico-deductive process and gave rise to the null hypothesis testing procedures still in use today, including within the field of creativity research.

Among creativity researchers, deductive reasoning is typically considered a highly convergent form of thinking (Weisberg, 2018), both because it is a constrained and formalized process, and also because deductive conclusions, assuming no reasoning mistake is made, must be true. In this way, deductive reasoning, when the context of problem-solving allows for it, is a highly effective method for converging on a truthful or meaningful conclusion. However, it is also likely that most real-world reasoning contexts do not necessarily afford very many opportunities for truly deductive thinking, because it is rare for reasoners to be certain of the veracity of their premises. If a reasoner's premises are less than certainly true, another form of reasoning, such as inductive or relational reasoning, will likely be more useful.

Inductive reasoning. In contrast to deductive reasoning, which begins with general premises that are assumed to be true, and proceeds to specific conclusions whose veracity is based on the truth of the premises, inductive reasoning begins with a number of specific observations about the environment and proceeds to the positing of a general premise that attempts to truthfully describe those observations. For example, if an elementary-school aged child has observed 50 swans in their life, and all of those swans have been white, that child might induct the general principle *all swans are white*. Of course, this general principle may or may not be absolutely true, but only reflects a probabilistic prediction on the child's part. In fact, a more formalized general principle drawn by this child may most appropriately be stated as, *based on my observations, all swans are probably white*.

It has been pointed out by scholars of scientific reasoning and philosophers of science that the creation of such general principles from specific observations more naturally describes the way science proceeds, in that scientists gather observations from empirical work, and attempt to form general theories that describe those observations (Dunbar and Klahr, 2012). Of course, the pervading role of deductive reasoning in science is also clear, in that the general premises formulated through empirical observations can and should be stated as hypotheses that could be disproven through further empirical observation. In this way, a movement between inductive and deductive reasoning processes allows science to move towards the discovery of principles that can be described as most likely to be true. From the perspective of creativity research, such a combined deductive and inductive reasoning process has the general goal of converging upon useful, optimized, and novel explanations for natural phenomenon.

Relational reasoning. Another reasoning process that allows for reasoners to converge on optimal or meaningful solutions to a given problem is relational reasoning, or the discernment of structural patterns among multiple pieces of information or mental representations of that information (Dumas et al., 2013). In this conceptualization, relational reasoning differs from the more basic form of pattern recognition and inductive reasoning in that it requires the identification of *higher-order relations*, or relations among relations among concepts.

For example, "protective covering" describes the first-order relation between the concepts *feathers* and *bird*, as well as the first-order relation between *fur* and *bear*. But the mapping of the higher-order analogical relation *feathers:bird::fur:bear* requires relational reasoning. Because such analogical reasoning is cognitively complex and requires a relatively high level of neurological development or working memory capacity, analogical reasoning problems have been historically utilized on intelligence or reasoning tests in education (Sternberg, 1977). But educators also capitalize on relational reasoning processes as a way to introduce new concepts to their students. For example, adolescents are often exposed to some aspects of cellular biology through analogies that map to domains in which they are already familiar. For instance, the mitochondria can be initially introduced to learners as being analogically related to a power-plant because it produces the energy that a living cell needs to function. In this way, a teacher draws on something their students already know (the power-plant) to introduce aspects of something they do not yet understand (the mitochondria).

In the analogical reasoning and creativity research literature, some scholars (e.g., Holyoak and Thagard, 1995) have pointed out that the mental leap required to map an analogy, especially if the concepts are relatively distant, bears some cognitive resemblance to the insight required for creative thinking. This initial observation has led to empirical work that has generally confirmed the hypothesis that relational reasoning plays a role in the creative thinking process, by allowing semantically distant, but structurally related ideas to be connected (e.g., Green et al., 2012). For this reason, the categories of convergent and divergent thinking are likely more porous in the case of relational reasoning than in the case of deductive or inductive reasoning. However, relational thinking certainly does not necessarily lead to original or novel ideas, instead, the mapping of structural relations may simply be a more elegant way of converging on an optimal solution or explanation in the reasoning context. In order to more definitively transcend convergent thinking and allow for creativity, thinking processes that are specifically divergent in nature must be employed.

Components of Divergent Thinking

Divergent thinking can be generally described as the mental process by which individuals or teams pose ideas that differ substantively from those previously posited, or that contain elements that are structurally different from the source-domain of the problem. One of the most famous divergent thinking tasks in the creativity literature is the Alternate Uses Task (AUT). In this task, participants are asked to generate as many novel uses for everyday objects as they can within a certain amount of time. For the given everyday object *book*, the response *read* would not be very divergent because reading is a typical use for a book, but the response, *throw like a frisbee* may be more divergent, because that use is not typical for a book. An individual's divergent thinking can be described along a number of dimensions that are generally concerned with both the quantity and novelty of the ideas produced. Here, four such dimensions will be briefly reviewed. Because these components of divergent thinking are described elsewhere in this encyclopedia, the description here is brief and in service of explicating the relations among creativity and reasoning (see Divergent Thinking).

Fluency. An individual or team's ideational fluency represents the quantity of ideas they produced during a divergent thinking session. In general within the creativity literature, a greater quantity of ideas is considered to be positive, because those individuals who produce very many ideas are also more likely to have produced more original, and even potentially more useful ideas (Dumas and Dunbar, 2014). In this way, a high quantity of ideas, produced via a highly fluent divergent thinking session is an important component of divergent thinking and creativity.

Originality. Clearly, producing a high quantity of ideas is not sufficient for being highly creative. In addition, the divergent thinking of an individual can be characterized by originality, which pertains to the novelty of the ideas produced. Although methods within the creativity literature for measuring the originality of a given idea or group of ideas differ, all center on the operationalization of the conceptual or semantic distance between the problem (e.g., the object-prompt in the AUT) and the proposed solution (e.g., a use of an object). In this way, originality can be conceived of as the divergent quality of a given idea, and perhaps the central requirement for divergent thinking and creativity.

Flexibility. In a situation where multiple ideas are produced in response to a prompt, the quality of the entire set of ideas can be described not only by the divergence between the prompt and the individual responses (i.e., originality) but also by the conceptual distance among each of the responses. Typically, an individual is considered a highly flexible thinker in the creativity literature if they are able to propose ideas that are drawn from a variety of different categories or domains but that all meaningfully pertain to the same prompt or problem-context. In contrast, even a highly original thinker may draw their original ideas from only one conceptual category, limiting the flexibility of their divergent thinking.

Elaboration. In addition to these three components of divergent thinking, individuals can also differ in the degree to which their ideas are rich in elaborative detail. For example, an individual who proposes ideas that consist of a number of specifically described elements may be more capable of creatively solving a problem than an individual who posits very vaguely described ideas. Such an elaborative quality may be specifically related to the prior knowledge that an individual brings to the divergent thinking context, but goes beyond that prior knowledge because it must essentially involve the detailed explication of ideas that are relatively original or novel to the domain in which the individual is working. In this way, elaboration influences the divergent quality of ideas posited during divergent thinking.

The Threshold Hypothesis and Creative Potential

Neither the convergent reasoning processes of deductive, inductive, and relational reasoning, nor the divergent thinking components of fluency, originality, flexibility, and elaboration are sufficient in themselves to constitute creativity. Instead, both convergent and divergent thinking processes are needed to produce ideas that are simultaneously novel and effective. For this reason, divergent thinking ability has been referred to as *creative potential* within the creativity research literature (e.g., Lubart et al., 2010), with the term implying that divergent thinking opens the door to creativity by allowing an individual to flexibly posit a number of original ideas, although only some of them (or none of them) might be effective, meaningful, or useful enough to constitute a truly creative solution.

On the other hand, a certain level of convergent thinking ability is also a necessary but not sufficient condition for creativity. For those in the creativity research field who focused their research on the convergent thinking associated with logic, reasoning, or intelligence (e.g., Karwowski et al., 2016), the *threshold hypothesis* states that such convergent thinking skills support creativity, but only up to a point on the distribution of convergent thinking. After an individual has the requisite amount of convergent reasoning ability, the likelihood that they will be capable of producing highly creative work is determined by their divergent thinking ability. The specific threshold at which convergent thinking abilities no longer support creativity is the focus of an ongoing debate in the literature, but it is most typically considered to be slightly higher than one standard deviation above average ability, or approximately 120 on the scale of traditional intelligence tests. In addition, some evidence exists that some fluid reasoning abilities, in particular relational reasoning, support divergent thinking processes themselves (e.g., originality), but also only up to a point (Dumas, 2018).

However, it should be noted here that, within the current literature on the threshold hypothesis, the evidence for or against the veracity of the hypothesis has been mixed depending on the particular creative outcome (e.g., creative achievement or divergent thinking) and the particular intellectual measure (e.g., fluid or crystallized intelligence) used in the research. For example, the threshold hypothesis has been more likely to be upheld in research studies that utilize more crystallized measurement tools

such as creative achievement checklists and measures of domain-specific prior knowledge (Sligh et al., 2005) than it has been in research using primarily measures that rely on fluid mental processes, such as divergent thinking tasks and visuo-spatial reasoning problems. Such a pattern may suggest the critical role that prior domain-specific knowledge plays in the creative process in that it allows for more effective convergent reasoning and logical problem-solving, which in turn supports creativity if it is combined with the creative potential of divergent thinking processes.

Interestingly, both the current conceptualization of divergent thinking as creative potential and the specific formulation of the threshold hypothesis among intellectual and creative abilities imply the same relation between logic and reasoning, on the one hand, and creativity on the other: a necessary but not sufficient relation. So, the evidence simultaneously suggests that both divergent thinking and logical reasoning are necessary for creative achievement, but neither is sufficient in and of itself. For this reason, it appears possible to more fully unify the psychological conceptualizations of logic and reasoning with that of creative thinking in that, as the introduction to this chapter implied, the process of producing a creative (i.e., both original and useful) idea could be conceptualized as a special case of the reasoning or problem-solving process in which the problem solution is original.

Future Directions for Investigating Creativity and Reasoning

Although there are thousands of published psychological investigations on the way in which reasoners employ deductive, inductive, and relational reasoning to converge on solutions to a problem, and there are also very many published studies on the process of divergent ideation, there is comparatively far fewer extant work that specifically examines the way individuals or teams utilize both logical reasoning process and divergent thinking processes to creatively solve a complex problem. Research on creative problem-solving may be less common because of certain methodological difficulties, for example the necessity to pose problems to participants that cannot be simply scored as right or wrong, but need to be evaluated more richly for levels of originality or effectiveness. In addition, formulating problem-tasks that are appropriate for creative problem-solving in that they simultaneously require a high level of convergent reasoning skills and prior knowledge, but also are open-ended and novel enough to inspire creativity, will likely be a challenge for researchers. For these reasons, an *in vivo*, or naturalistic observation approach, in which participants are engaged in real-world creative problem-solving while researchers observe, may be a fruitful research paradigm for investigating the interplay among logical reasoning and divergent thinking. Such an approach has been previously used to investigate convergent processes such as relational reasoning (Dumas et al., 2014) and may be extended to include a focus on creativity. In addition, much real-world creative problem-solving may unfold in group settings as teams work together to find an original and effective solution.

But, the way in which group discourse processes impact divergent thinking is not currently well understood in the creativity research field. The number of group members, the relationships among them, and a vast number of socio-emotional, linguistic, and contextual factors may play a role when groups are engaged in creative problem-solving, and therefore opportunities to examine the influence of these factors currently abound. Moreover, from an educational or perspective, how specifically can individuals or groups be taught to apply their convergent and divergent thinking skills more effectively in the creative problem-solving context? Therefore, the principal focus of this entry—the relations among logic, reasoning, and creativity—currently raises many more questions than answers. Indeed, it is not currently known, from a psychological mechanistic perspective, how original and effective (i.e., creative) ideas arise from a process of creative problem-solving. However, such a process certainly requires deductive, inductive, and relational reasoning as well as divergent thinking in varying amounts, in varying orders, and over varying lengths of time, depending on the problem-solving task and context. Such an open area for research should excite creativity researchers, because there is much to learn, and many ways to apply our own creative thinking as researchers, in the intersection of creativity and reasoning research.

Creativity and Age

There is a widespread belief that creativity is associated primarily or exclusively with youth (e.g. see [Galenson, 2016](#)). This belief might seem odd when we think of some creative landmarks of the modern era. Darwin published *The Origin of Species* at the age of 50. Tolstoy published *Anna Karenina* at 49, Dostoevsky *The Brothers Karamazov* at 59, Twain *Adventures of Huckleberry Finn* at 50, Proust the final volume of *In Search of Times Lost* at 56, and Woolf *To the Lighthouse* at 45. Rodin completed the *Monument to Balzac* at 49. Robert Frost published “Stopping By Woods on a Snowy Evening” at 48, and Elizabeth Bishop “One Art” at 65. Frank Lloyd Wright completed the New York Guggenheim at 76, Le Corbusier Notre Dame du Haut at Ronchamp at 63, and Frank Gehry the Guggenheim Bilbao at 64. Alfred Hitchcock directed *Vertigo* at 59, and *Psycho* at 61; Clint Eastwood directed *Unforgiven* at 62, and *Million Dollar Baby* at 74. Irving Berlin wrote “God Bless America” at 51, and “White Christmas” at 54.

Perhaps these are mere anomalies, isolated examples of creativity at older ages? Quantitative evidence says otherwise. A recent study of nearly 3000 physicists found that a scientist’s most highly cited publication had an equal probability of being published at any point within the sequence of papers the scientist published ([Sinatra et al., 2016](#)).

Conceptual and Experimental Innovators

Creativity is not the prerogative of the young, but can occur at any stage in the life cycle. There is not a single kind of creativity, but in virtually every intellectual discipline there are two different types of creativity, each associated with a distinct pattern of discovery over the life cycle. The bold leaps of fearless and iconoclastic young *conceptual* innovators are one important form of creativity. Archetypal conceptual innovators include Einstein, Picasso, Eliot, Hemingway, Warhol, Godard, Plath, and Dylan. But there is another, very different type of creativity, in which important new discoveries emerge gradually and incrementally from the extended explorations of older *experimental* innovators. Darwin, Tolstoy, and the other late bloomers listed in the second paragraph of this article were all important innovators of this kind.

The differing life cycles of conceptual and experimental innovators reflect fundamental differences in both the nature of their creativity and the means by which they achieve it. Conceptual innovations express ideas or emotions. Conceptual innovators determine the purpose of a work before they begin executing it, so they typically plan their works carefully before executing them systematically. The clarity of their intent can allow them to feel that they have fully realized their objectives for a particular work. Conceptual innovations often appear suddenly, as a new idea can yield a novel work that fully expresses the idea.

In contrast, experimental innovators are concerned above all with perception. They work inductively to develop new methods based on extended observation and experimentation. They privilege process over products, and hope to make discoveries in the course of working. Their vague goals leave them feeling perennially dissatisfied with their work, but uncertain how to improve it. Their uncertainty leads them to proceed tentatively and incrementally, by trial and error. Experimental innovations consequently emerge gradually, over an extended period; they are rarely embodied in a single work, but appear piecemeal in a body of related works.

Conceptual innovations are surprising combinations of elements that had previously been unrelated. The most radical conceptual innovations combine elements that had previously existed in different domains, and the ability to connect these requires imagination and intellectual freedom. This is why radical conceptual innovation is typically the prerogative of recent entrants into a discipline, who have not had time to become constrained in their thinking by growing accustomed to following the domain’s established conventions and practices. Because most new entrants into intellectual disciplines are young, important conceptual innovations are usually made at early ages.

Experimental innovators want their products to emerge from sustained direct observation of reality. Their late innovations are generally their most powerful because they are based on greater accumulated knowledge, and formulated with greater technical mastery developed over long periods of study. The experimental innovations of cautious old masters often arrive gradually and unobtrusively, and may be long overlooked and undervalued (Galenson, 2018). Recognizing that important innovations need not be blatant, but can be subtle and inconspicuous, can help us correct the error of the longstanding scholarly belief that creativity is greatest in youth. It is consequently worth pointing out the specific mechanisms that connect age with experimental creativity. This can be done by considering the examples of some important experimental innovators.

Cézanne

The single year from with Paul Cézanne's work is most frequently illustrated in textbooks of art history is 1906 – the last year of his life, when he was 67. Two years earlier, in a letter to a younger friend, Cézanne (1995, pp. 299, 302, 315) assessed his own achievement:

In your letter you speak of my realization in art. I believe that I attain it more every day, although a bit laboriously. Because, if the strong feeling for nature – and certainly I have that vividly – is the necessary basis for all artistic conception on which rests the grandeur and beauty of all future work, the knowledge of the means of expressing our emotion is no less essential, and is only to be acquired through very long experience.

A few months later, Cézanne wrote to the painter Emile Bernard that “I progress very slowly, for nature reveals itself to me in very complex ways; and the progress needed is endless.” The next year, Cézanne again told Bernard that he believed he had made some progress, “rather slow,” in his latest works, then added, “It is, however, very painful to have to state that the improvement produced in the comprehension of nature from the point of view of the picture and the development of the means of expression is accompanied by old age and a weakening of the body.” These letters expressed Cézanne's conviction that above all two elements – the acuity of his perception of the subject, and the development of a technique that would allow him to express that perception – were critical to the improvement of his art, and his belief that both of these elements could only be the products of long and painstaking study. These letters also expressed his cautious judgement that he was making progress. Scholars have agreed, as Roger Fry (1984, p. 41) wrote of his “long research of an ultimate synthesis which unveils itself little by little from the contemplation of the things seen,” and Meyer Schapiro (1952, p. 27) declared that “the years from 1890 to his death in 1906 are a period of magnificent growth.”

Twain

Mark Twain emphasized that his fiction always grew out of things he knew directly – “life with which I am familiar” – so it is not surprising that he considered experience “an author's most valuable asset.” For Twain, experience was what brought fiction to life, and it could only be the product of deep knowledge of the subject: “Almost the whole capital of the novelist is the slow accumulation of unconscious observation.” This took time: “The life, the soul, the genius of a people are realized only through years of absorption.” In addition to the experience of life, the writer needed experience of his craft, which also required time: “Every man must *learn* his trade – not pick it up. God requires that he learn it by slow and painful processes. The apprentice hand in blacksmithing, in medicine, in literature, in everything, is a thing that can't be hidden.” (Dawidziak, 1996, pp. 15, 47–55). T.S. Eliot recalled that reading *Tom Sawyer* – “a boys' book, and a very good one” – had not prepared him for *Huck Finn*, “the only one of Mark Twain's various books which can be called a masterpiece.” He contended that Twain's growth in the eight years between the two books was not only in his skill in the use of language, but in his creation of the form of the narrative: “We look at Tom as the smiling adult does: Huck we do not look at – we see the world through his eyes. The two boys are not merely different types; they were brought into existence by different processes.” This created a basic difference in the depth of characterization: “Huck's persisting admiration for Tom only exhibits more clearly to our eyes the unique qualities of the former and the commonplaceness of the latter.” Twain's mature mastery of language allowed him to create Huck consistently and convincingly: “there is no exaggeration of grammar or spelling or speech, there is no sentence or phrase to destroy the illusion that these are Huck's own words.” Twain created Huck experimentally, for “*Huckleberry Finn* is not the kind of story in which the author knows, from the beginning, what is going to happen.” Twain's experience, both of writing and of life growing up on the Mississippi, allowed him to give a simple boy a quality that made him one of fiction's greatest characters: “Huck has not imagination, in the sense in which Tom has it: he has, instead, vision. He sees the real world; and he does not judge it – he allows it to judge itself” (Bloom, 2006, pp. 33–41).

Darwin

Charles Darwin's career was based on the conviction that theories should be the product of deep and detailed knowledge. At the age of 22, he accompanied a Cambridge geology professor on a trip to Wales. Darwin (2005, pp. 59, 132) was “utterly astonished” when the professor dismissed a single anomalous discovery as uninteresting, because of the lack of related evidence that the oddity was of

real significance. The lesson was lasting: “Nothing before had ever made me realize ... that science consists in grouping facts so that general laws or conclusions may be drawn from them.” At 62, Darwin gave a concise statement of his formula for creativity, in a letter congratulating his youngest son on passing a college exam. The boy was not a distinguished student, and Darwin’s own mediocre record as a student clearly allowed him to identify with Horace. His encouragement to his son stressed that creativity did not depend solely on intelligence:

I have been speculating last night what makes a man a discoverer of undiscovered things, and a most perplexing problem it is. Many men who are very clever – much cleverer than discoverers – never originate anything. As far as I can conjecture, the art consists in habitually searching for causes or meaning of everything that occurs. This implies sharp observation and requires as much knowledge as possible of the subject investigated.

Steve Jones (2011, pp. x–xi) recently emphasized the vast amount of evidence Darwin produced, and its far-reaching impact:

His lifelong labors – six million words in nineteen published works, hundreds of scientific papers, and fourteen thousand letters – generated an archipelago of information, a set of connected observations that together form a harmonious whole. Biology emerged from that gargantuan effort as a unitary subject, linked by the great idea of common ancestry, of evolution. The volumes written in Down House made sense of a whole new science and enabled its students to navigate what had been an uncharted labyrinth of shoals, reefs and remote islets of apparently unrelated facts.

Jones believed that Darwin “became a better scientist as he grew older for he began to test ideas with experiments, many far ahead of their time, rather than collating the results of others.” Antonello La Vergata observed that Darwin’s intellectual ability itself developed over time: “Darwin students today generally agree that Darwin’s theory was constructed, not discovered, and that it was the result of the evolution of a creative system: Darwin’s mind” (Kohn, 1985, p. 934).

Shakespeare

Harold Bloom (2002, p. 18) contended that the uniqueness of Shakespeare’s genius was in peopling a world with “men, women, and children preternaturally natural. Cervantes rivals him with two giant personalities, Don Quixote and Sancho Panza, but Shakespeare has hundreds.” Shakespeare was an experimental innovator; Stephen Greenblatt (2004, p. 299) observed that his achievement was “not a sudden, definitive innovation, but the subtle refinement of a particular set of representational techniques.” T.S. Eliot considered Shakespeare the greatest of poets and dramatists, and never stopped pondering the nature of his development, which served as a focal point for Eliot’s consideration of the relationship between age and creativity. Eliot marveled at the “slow, continuous development of mastery of his craft of verse,” that never ceased: “To the last Shakespeare is inexhaustible. Whatever he did was new” (Kermode, 1975, p. 250; Ricks, 1996, p. 392). Eliot contrasted Shakespeare’s creative life cycle with that of a transgressive young genius who was his exact contemporary:

We can also observe ... that the plays of Christopher Marlowe exhibit a greater maturity of mind and of style, than the plays which Shakespeare wrote at the same age: it is interesting to speculate whether, if Marlowe had lived as long as Shakespeare, his development would have continued at the same pace. I doubt it: for we observe some minds maturing earlier than others, and we observe that those which mature very early do not always develop very far.

Eliot thus recognized the difference between the life cycles of conceptual and experimental poets. Reflecting on the quality of maturity, Eliot remarked that Shakespeare’s greatness not only grew as the writer aged, but became more apparent to the reader as he himself aged: “No reader of Shakespeare ... can fail to recognize, increasingly as he himself grows up, the gradual ripening of Shakespeare’s mind” (Kermode, 1975, p. 117). In his last public lecture, at 73, Eliot (1965, p. 23) remarked that “So great is Shakespeare ... that a lifetime is hardly enough for growing up to appreciate him,” and in one of his last essays he declared that “of Shakespeare, the development of one’s opinions may be the measure of one’s development in wisdom.” The extended and gradual development of the experimental Shakespeare was alien to the conceptual Eliot, who considered it no less than miraculous that a poet “should find something new to say, and say it equally well, in middle age.” The conceptual Eliot’s own creative life cycle had followed a very different path, and the subject must have been an uncomfortable one in view of Eliot’s awareness of the loss of his own early creativity. But Eliot was too perceptive a reader not to recognize the growth of Shakespeare’s art over the course of his life, and too principled a critic not to ponder the ways in which his creativity grew with age.

Dickens

The greatness of Charles Dickens’ experimental art was a product of perception: the novelist Angus Wilson noted that “he had a marvelous ear; but, I believe, an only just less marvelous eye” (Ford and Lane, 1961, p. 379). Dickens’ genius lay in making readers see and hear his people. Thus T.S. Eliot compared his creation of characters to Shakespeare, “in that a single phrase, either by them or about them, may be enough to set them wholly before us” (Ford and Lane, 1961, p. 152). Wilson reflected that he was haunted “by

scenes and characters from Dickens' novels," but that this "obsessive power" of the novels "does not derive from their total statements; it seems to come impressionistically from atmosphere and scene which are always determinedly fragmentary" (Ford and Lane, 1961, pp. 375–76).

Dickens' greatest weakness was his plots. G.K. Chesterton facetiously contended that *The Pickwick Papers* was not a novel, for all novels must have an end, and *Pickwick* lacked one: "The point at which ... we find the printed matter terminates is not an end in any artistic sense of the word. Even as a boy I believed that there were some more pages that were torn out of my copy, and I am looking for them still" (Ford and Lane, 1961, p. 109). Dickens suffered from the experimental affliction that as his characters developed, they would not obey his plans for them: his eldest son reported that he had "often and often, heard him complain that he could not get the people of his imagination to do what he wanted, and that they would insist on working out their histories in *their* way and not *his*" (Collins, 1981, p. 120). And so Dickens' friend Edward Bulwer described Dickens "groping his way" through his manuscripts, working out the meanings of his novels as he wrote them (Douglas-Fairhurst, 2011, p. 199). Dickens' flexibility in plotting was such that he actually changed the ending of one of his greatest novels in response to a criticism by Bulwer. Thus Dickens wrote to John Forster that "You will be surprised to hear that I have changed the end of *Great Expectations* ... Bulwer so strongly urged it on me, after reading the proofs, and supported his view with such good reasons, that I resolved to make the change" (Forster, 1969, p. 289). Dickens published the revised ending in 1861, but ever since Forster revealed the original ending in 1874, generations of critics and scholars have debated the relative merits of the two versions. One of these scholars recently observed that revising the conclusion may have seemed "palatable" to Dickens because he had already significantly altered the first ending before Bulwer objected to it (Bloom, 2000, p. 177).

Among Dickens' great late achievements were *Great Expectations*, which he published at 49, and *Our Mutual Friend*, at 53. His art had developed in a number of ways over time. He improved his organization and plotting. Daniel Burt observed that "There is perhaps no better illustration of the remarkable development of Dickens as a novelist than by a comparison between the exuberant, picaresque improvisation of *The Pickwick Papers* [published at 25] and the taut control of *Great Expectations*" (Burt, 2004, p. 71). Dickens also refined his mastery of characterization. A key element of Dickens' success in creating vivid characters lay in his ability to give his fictional people individualized habits of speech, or idiolects. Robert Golding's linguistic analysis demonstrated that Dickens' use of this device grew more effective over the course of his career, as "the artistry revealed in their development and utilization makes decisively clear the author's gradual progress towards a bettering of his fictional art." Whereas in his early novels only a few characters had distinct personal idiolects, "in the works of the final period it was no longer ... a group of leading figures with very pronounced idiolects being supported by a cast of typified 'also-rans,' but one of a world in which each separate character is the possessor of a sharply delineated speech idiom which cannot be ignored." The richness of the later novels was a product of a gradual and progressive "stylistic transformation which took in Dickens' fictional writing as a whole, one which finally succeeded in merging all the elements involved – including the idiolects – into a finely balanced whole." (Golding, 1985, pp. 213, 219, 228).

Bishop

Late in his life David Kalstone (1989, pp. x–xi) set out to write a book about the generation of American poets who came of age after World War II, but as he worked, Elizabeth Bishop "eventually took over my book." The manuscript he left unfinished when he died was about "the steady growth of an extraordinary mind." The poet Thom Gunn (1993, pp. 78–79) recalled that when he first met Bishop, he felt that there was a depth in her personally that had not gotten into her poetry, but when he read *Geography III*, the last of her books published in her lifetime, "all at once everything was changed ... It was only ten poems long, and yet its achievement was such that it retrospectively altered the emphasis and shape of an entire career." Thomas Travisano (1988, pp. 154–205) pointed to specific ways in which Bishop's work developed over time. Her idiomatic language and conversational voice grew more relaxed. Her understated treatment of details of everyday life grew subtler. The timing of her poems increasingly allowed images to emerge gradually, as if the poem were being composed as the reader examined it. The tone of her writing became increasingly elegiac, so that even her most personal poems were not confessional in the standard sense: her meditations dealt with not only personal loss, but with the universality of loss. She treated humble and overlooked subjects, finding "[a]mongst the discarded and ignored ... examples of integrity, dignity, courage, humor, and grace." These qualities made Bishop's late poetry an inspiration to Gunn and other young poets who wanted to make their art from careful observation of life. Bishop had a profoundly experimental distrust of theorizing about poetry. But late in her life, in a letter to a literary scholar she came close to a generalization about why art might grow with the accumulation of knowledge and experience: "Well, it takes an infinite number of things coming together, forgotten, or almost forgotten, books, last night's dream, experiences past and present – to make a poem" (Bishop, 1994, p. 621).

Aging Gracelessly

In contrast to the examples of great experimental innovators considered above, old age has rarely been a time for major discoveries by conceptual innovators. A central problem is that the accumulation of experience in a discipline is the enemy of the radical departures from existing approaches that constitute conceptual creativity. The ability to perceive these typically diminishes in proportion to the time an artist or scholar spends considering a particular problem, because this time creates habits of thought that constrain the formulation of novel ideas.

It might be thought that conceptual young geniuses would be well advised to change their ways as they grow older, in order to change into experimental old masters. But historical evidence, which reveals very few cases in which innovators have made important contributions both conceptually and experimentally, suggests that this transformation is more easily said than done. Edouard Manet was one of these rare exceptions. Thus he made his famous *Olympia* by a conceptual process at the age of 31, then made his no less celebrated *Bar at the Folies-Bergère* 19 years later, by an experimental process that involved radical changes in the course of executing the painting (Galenson, 2006, pp. 51, 57). Manet's strong friendship with Claude Monet and the other members of the experimental Impressionist group may have been responsible for his evolution away from the careful preconception of his early masterpiece to the improvisation of his late one. But the rarity of his achievement points to the great difficulty of changing not only a way of working, but of thinking, from the clarity of a deductive conceptual approach to the uncertainty of an inductive experimental one.

A different path for aging conceptual innovators would be deliberately to make a novel conceptual departure in old age, completely different from their earlier contributions. The difficulty of doing this successfully is again suggested by how rarely this has occurred in the past. Two successful cases can be cited here, that coincidentally both took place at the age of 56. Thus Pablo Picasso, who had startled the art world with his *Demaiselles d'Avignon* at 26, produced *Guernica* 30 years later, and Gerhard Richter, who had pioneered European Pop art in his 30s, two decades later produced a series of 15 paintings from photographs of three deceased members of the Baader-Meinhof terrorist group. Picasso was outraged by the obliteration of a Basque town by German bombers acting for the Spanish fascists, just as Richter was by the deaths of the terrorists in a German prison (Galenson, 2009, pp. 139–40). The two artists' reactions to these shocking events was so strong that it jarred them out of their normal habits in the selection of subject matter, and this resulted in novel and important contributions.

Significant cases of conceptual creativity in old age are rare. Few aging conceptual innovators have had younger experimental colleagues as great as the Impressionists, and few conceptual artists have been able to make constructive responses to external events that shocked them. The loss of creativity was true even of as towering an innovator as Albert Einstein, who produced one of the greatest of all scientific breakthroughs at the age of 36, then spent the remainder of his life refusing to accept the next intellectual revolution created by younger physicists. Among the many scholars who have pondered Einstein's stubborn refusal to accept quantum mechanics, his friend and biographer Abraham Pais (2005, pp. 463–64) speculated that "making great discoveries can be accompanied by trauma, and ... the purity of Einstein's relativity theories had a blinding effect on him."

Creativity in Old Age

The belief that creativity diminishes with age is based on the misconception that the accumulation of knowledge and experience serves only to reduce the flexibility, and consequently the creativity, of the old. Greater knowledge, and associated entrenched habits of thought, do appear to constrain conceptual innovation, for they create barriers to the extreme simplifications that often characterize conceptual creativity, and they tend to erode the brash self-confidence of the cocksure young prodigy who can make bold leaps into the unknown because he is not yet aware of, and intimidated by, the complexity of his discipline.

But the recipe for experimental innovation is very different. Great experimental innovators develop not only vast stores of knowledge – "as much knowledge as possible of the subject investigated," in Darwin's words – but also the technical means by which to turn it into a novel contribution – Cézanne's "knowledge of the means of expressing." Both the accumulation of great knowledge and the construction of new technical means are "only to be acquired through very long experience," in Cézanne's words, and this implies that their greatest results will almost always appear late in a career. In the presence of appropriate technical expertise, greater knowledge affords the experimental innovator a larger and more trustworthy foundation for generalizations, to support ever broader and more far-reaching conclusions. A key contributing factor is that many great experimental innovators, like Cézanne, Darwin, Shakespeare, and Bishop, are "inexhaustible," never lose their fascination with their chosen discipline, and consequently never cease developing intellectually.

Old age and great experience may be lethal to the creativity of conceptual young geniuses, but they are the lifeblood of the innovations of experimental old masters. This analysis would come as no surprise to Paul Cézanne, Charles Darwin, Mark Twain, Elizabeth Bishop, or any other great experimental innovator. Among the latter was Louise Bourgeois (1998, pp. 318–19), a great experimental sculptor, who once declared, "I am a long-distance runner. It takes me years and years and years to produce what I do." Bourgeois made her greatest work after the age of 80. When she was 84, and an interviewer asked whether she could have made one of her recent works earlier in her career, she replied, "Absolutely not." When he asked why, she explained, "I was not sophisticated enough."

In order to understand better the creative development of children, adolescents and adults, it is necessary to compare their creativity at different ages. To do this, several methodological approaches are possible. Cross-sectional research compares age groups of different participants, observed only once at the same time, on the same measure, such as creative potential or creative achievement. In cross-sectional studies, there are as many samples as there are age groups, which makes it possible to coarsely trace development for a population. Based on these findings, researchers infer the development of creative potential on the basis of a data collected on different children. However, this approach does not make it possible to determine whether individual development is similar to mean developmental patterns observed at the group level. A second, potentially more powerful methodological approach is the use of longitudinal studies, which is the focus of this contribution. Longitudinal studies consist of following participants individually during the developmental period of interest through repeated examinations. Accordingly, comparisons by age are based on behaviors collected from the same participant. In this approach, intra-individual variability can be observed. Longitudinal studies make it possible to make the link between potential in childhood and achievements in adulthood. Researchers could also examine protective or risk factors for the development of creativity or evaluate the impact of a training program.

The exact longitudinal approach is not always the same, depending on the questions raised by researchers: some studies are short (few weeks), some are long (several years), some are prospective, others are retrospective (biographical studies). Thus, the duration and the number of intermediate examinations (present or not) depend on the researcher's objective.

In this contribution, we categorize longitudinal research. First, we will focus on retrospective, biographical studies. Second, we examine large-scale longitudinal studies from childhood to adulthood, which do not always focus exclusively on creativity. In the third part, we will examine the development of creative potential, in particular, with a focus on divergent thinking in many cases. In a fourth section, we will discuss studies that seek to identify factors that may impact creative potential. Finally, in the last part, we will focus on research related to education because creativity is considered today as a 21st century skills and teachers are invited to develop children's creative potential.

Bibliographic Studies

In retrospective studies, researchers are interested in variations in creativity over the careers of exceptional creators, whether during their childhood (Diezmann, 2008) or during adulthood for the majority of research (Caslistl, 2018; Simonton, 1984; 1997). There is also the question of tracing life paths and prerequisite characteristics that can explain the identification of creative works (Kohanyi, 2005).

Simonton (1984), following work by Lehman, investigated creativity in adults over their career, in terms of quantity and quality of their contributions. Regarding the quantity of creative productions, it is typical to count a creator's productions over a given period (e.g., 10 years). Generally speaking, the amount of creative production increases rapidly with age, reaching a peak around 40 years, and then productivity gradually decreases. However, differences are observed according to the creative domain. For example, Kozbelt (2008) observed a peak in the success rate of classical composers around 50 years of age, whereas the peak for mathematical researchers was around 30 (Simonton, 1984). Concerning the quality of productions, Simonton's results (1997) highlight a constant relationship throughout individuals' professional career between major works and creative activity. However, several authors (see Caslistl, 2018; Simonton, 1997) consider creativity to show content variation depending on the age of artists, with some studies suggesting a shift in topics and style, called "old-age style"¹ in some studies of artists and writers.

¹The "old age style" is characterized by (1) the importance of subjectivity rather than objectivity; (2) unity, harmony and integration of seemingly contradictory ideas; (3) the presence more important of aging theme.

Retrospectively, it is also possible to interview creators by focusing on the factors that have influenced their career. For example, Kohanyi (2005) conducted interviews with journalists and writers; both groups indicated that they felt different from other children (solitary, introversion) but distinguished themselves in terms of cognitive factors (aesthetic aspect of language for writers vs. socio-political sphere for journalists) and family environment (family centered on children for journalists vs. stressful families for writers).

Longitudinal Studies to Predict Adult Creativity

One objective of the longitudinal studies is to explore what factors can impact creative achievements in adults. In this research, the focus is often, at least, on two measures, one in childhood/adolescence or in young adults and the second in mid-life. Longitudinal research is important in a number of ways and sometimes researchers share their data in order to have an overall view on different aspects of development.

The Study of Mathematically Precocious Youth (SPMY) began in 1971 with the aim of better identifying the educational needs of young people with high potential. Teenagers were selected at ages 12–13 for their high verbal or/and mathematical abilities, measured by the SAT, used for entry to college. Ability at age 13 was related to patterns of creativity in adulthood, which vary in terms of the creative domain (science or human science) and the number of productions (see Park et al., 2007). In the same vein, Runco and Albert (2005) conducted a 20-year longitudinal study of high-potential teenager boys selected for either their IQ or their math and high-science abilities. Results highlighted relationships concerning wellness, sociability, and flexibility. Moreover, the creative performance of adolescents correlated strongly with the creative performance of their parents.

In Germany, Kandler et al. (2016) examined data from two partially overlapping longitudinal studies, including twins (GOSAT - German Observational Study of Adult Twins and BilSAT). During the third wave of evaluation on the BilSAT protocol, a graphic creativity test was administered whereas on previous waves, only questionnaires were used. The results highlight that perceived creativity correlated with personality dimensions of openness and extraversion. Graphic creativity correlated with the openness dimension of the personality as well as intelligence. The results show also that the primary source of creative performance variability was the environment.

In the United States, a 30-year longitudinal study was conducted, taking into account creativity in a female population (Mills Study of Creative Personality in Women). Women were seen at 21 and then at 52 years old. During these two measurement times, personality, motivation, cognitive and affective styles and creativity were evaluated; creative potential predicts creative achievements, and some dimensions of personality (creative temperament, originality, complexity, tolerance of ambiguity), professional aspirations (ambition, persistence) as well as cognitive and emotional styles predict creative achievements.

Feist and Barron (2003) conducted a follow-up study of eighty people, tested initially at 27 years old (assessing their intellectual skills, personality and creative potential) and then again at 72 years old (assessing their personality and creative professional success). The results show that creative potential and intellectual skills predict job success in terms of creative achievement. In addition, some personality variables (including tolerance of ambiguity) explain an additional 20% variance of job-related creative achievement.

Karwowski et al. (2017) conducted various studies in adolescents, young adults and middle-aged adults. In a first set of studies, they highlighted that the frequency of creative activities at 52 years is predicted by intellectual efficiency, evaluated 40 years ago. Furthermore, in research on the link between the creative potential of young adults and creative achievements in adulthood, they found that this correlation was mediatized by a sense of self-efficacy and moderated by the perceived value of creativity (Karwowski and Beghetto, 2018).

Although previous research has generally shown a correlation between creative potential in adolescents or young adults and later life adult's creative achievement, Clapham et al. (2005) did not find support; they examined the link between creative potential of engineering students and their creative activities in their profession 15 years later but found no link, which may be explained in particular by the fact that creativity seems to be specific to the field and that the divergent thought test used was not related to the area of professional expertise of the participants.

In addition, it is important to note that there are various factors that can impact longitudinal studies such as “experimental death”: indeed, even if, at the start of a study, the sample is representative of the parent population, it is not necessarily the same at the end, some years later, because various factors that lead to loss of participants (some lose contact, move away, etc) and therefore the nature of the sample may have changed.

Development of Creative Potential

The main objective of this type of research has been to observe qualitative and quantitative changes in creative development. Indeed, the question of the existence of a general developmental profile of creativity was raised, and studies suggested the presence of phases of stability and temporary decline in creative performance during development.

The first consequential study on the development of creative performance in children was conducted by E. Paul Torrance in the 1960s in Minnesota, USA. One objective of this research was to develop tests, notably the *Torrance Test of Creative Thinking* (TTCT). The second objective was to characterize the development of creative performance of children, adolescents and young adults from elementary school to university. Students completed the different tests of creativity for several years (since elementary school). Moreover, Torrance noted creative accomplishments that each participant had achieved so far. Torrance linked the performances

obtained in TTCT (verbal and graphic), with creative achievement in everyday life (Torrance, 1981). Plucker (1999) continued this research by finding more than half of the individuals ($n = 220$) and counting each participant's number of publicly recognized creative productions (articles, awards, inventions). Plucker's analysis showed that around 50% of the creativity of the adult individuals is explained by scores on the divergent thinking tests administered while in elementary school. Plucker found that this contribution of divergent thinking to the variability of proven levels of creativity was three times greater than that related to IQ.

Cramond et al. (2005) Runco et al. (2010) reported 40 and 50 year follow-ups of the original Torrance data. Cramond et al. (2005) tracked the original Torrance cohort 40 years later in 1998 with a response of 99 participants. In this analysis, 5 indices of creative achievement were taken into consideration with a questionnaire to measure the quantity and quality of creative achievements. The authors used structural equations with eight predictors (intelligence, initial TTCT scores (fluidity, flexibility, originality, elaboration), TTCT scores three years later, the questionnaire results in 1980 and those of 1998. The best predictors of the *quantity* of creative achievement were IQ, fluency, and originality on the TTCT. For *quality*, it was IQ, flexibility and originality on the TTCT, and the creativity index. The authors highlight gender differences: IQ was more predictive of the creative achievements of women than men. Runco, Millar, Acar, and Cramond (2010) followed up on the original Torrance cohort 50 years later in 2008 with a response of 60 participants. The goal was to test TTCT's predictive validity. In this research, a composite score was created for the 4 TTCT indices (Fluidity, Flexibility, Originality, Elaboration). This composite score correlated with personal creative achievements ($r = .35$, $p = .04$) and public creations ($r = .30$, $p = .012$). The authors found gender differences: men showed more public creative achievements and women personal creative achievements. Moreover, there was a quadratic relationship between TTCT indexes and personal creative achievements, intermediate levels of divergent thinking characterized people with the highest creative output.

Concerning the development of divergent thinking, Torrance's results suggested three periods of temporary decline or slump (first grade, fourth grade and seventh grade). Torrance provided a social explanation for the periods of temporary declines. However, as will be seen in the next part, many longitudinal studies highlight the role of different factors, cognitive, conative and environmental (in line with a multivariate approach).

Factors that Impact the Development of Creativity

Longitudinal studies can also help to better identify the joint evolution of creativity with other factors, as creativity is multi-determined. Numerous studies, whether in children, adolescents or adults, examine cognitive factors, in order to check the possible links between specific or general cognitive factors and creative performance or to see the joint evolution of different constructs. In this regard, several studies have sought to identify the reasons underlying the fourth-grade slump. Notably, Lin and Shih (2016) focused on the role played by fluid intelligence (measured by a reasoning task) and crystallized intelligence (measured by a vocabulary task) on two types of creativity tests, open problems (divergent thinking) and closed problems (traditional convergent thinking). Their findings show that only fluid intelligence has a link to creative performance, and in particular, children are more successful at closed problems when using type 2 reasoning (logic), whereas children are more successful at open problems when using type 1 reasoning (intuition). In the same vein, Fürst et al. (2012) have been particularly interested in the use of processes of generation and selection in art classes among young adults. Their results show that in the early session, the idea generation process is very important and then gradually decreases over the sessions whereas the idea selection process follows an inverted U curve highlighting the importance of this process in the middle-sessions.

Intelligence is a highly studied factor in terms of its connection with creativity. Welter et al. (2016) sought to test the threshold theory that there would be a correlation between creativity and intelligence up to an IQ of 120 and that thereafter there would be no link. To do this, their participants completed Raven's matrices as well as a graphical creativity test (TCT-DP), at the beginning and end of the school year. The results do not verify the threshold theory in this population and authors note variations influenced by the level of education of children and their gender.

In terms of conative factors, there is research on the link to moral development, as it is often necessary to think outside the box in order to propose new solutions. Niepel et al. (2015) who were interested in the link between ethical decision-making and creative performance of children aged 10 to 14 did not find a relationship between these two constructs, even when controlling for level of reasoning.

Some longitudinal research has also looked at the role of emotions. For example, to explain the decline in performance at seventh grade, Hee and Wong (2015) checked on the role of stress when children have to change grade level associated with a change of institution. Thus, they compared the level of stress and children's creative performance who were in this situation as well as children the year before and the year after. The results show that stress and therefore negative emotions are related to the slump in creative performance.

There is little consensus on the results of cross-sectional studies on the role of emotions. However, it seems that positive emotions play a major role in divergent thinking tasks. Rogaten and Moneta (2015) interviewed 130 students, in the first and second semesters, about their emotions over the past six months and their perception of their creativity. The results of this research highlight a positive relationship between positive emotions and creative cognition: the more positive emotions students experience and the more creative cognition they report.

Karwowski (2016) has been particularly interested in the evolution of two concepts, creative self-efficacy and creative personal identity, especially among teenagers and adults. An adolescent sample, aged 13 to 15 years, was seen at six months' intervals and the results show a stability of these two constructs. For participants aged 15 to 60 years who were seen 20 months apart, results show a change between the two measures, which can be explained by the life changes they tend to experience.

The environment is the last major factor that can impact creative performance. The family environment is the first to play a role. Harrington et al. (1987), in a longitudinal study, highlighted the importance of a supportive family environment for the development of creative performance, by maintaining constant gender, intellectual level and creative potential. They found a link between children's creative potential and their parents' creativity. Russ (2003) worked on the importance of pretend play in young children and highlighted that it predicts divergent thinking performance as well as fantasy of children's responses. Brook (1973) conducted a longitudinal family follow-up between children measured at 21 months and 18 years and then re-contacted "children" at 30 years with a questionnaire about artistic activities. She found that during childhood, gender differences were important in artistic activities and that this difference persisted in adulthood. Women who have had artistic activities during childhood described themselves as more unsociable, with a strong intellectual orientation whereas the men reported having a rich emotional life.

Among adults, the job environment has primary importance for creativity research. Longitudinal studies highlight the importance of social interactions and, more specifically, different forms of conflict or the pressure from the environment that reduce creative performance. Some studies show additionally the importance of taking a break to improve creative performance, as people who went on holiday improved their flexibility in a divergent thinking task.

Training Studies, Workshop Effects and Teachers' Mediation

Given the importance of creativity in the school environment, numerous research studies have sought to assess (1) the teachers' role and (2) the effect of workshops, pedagogical practices on the development of creative performance.

Transmission by Teachers

Teachers are primary mediators of thinking and learning for their students. Indeed, Fleming et al. (2016) have been interested in the link between teachers and their students, showing the importance of the presence of imagination and art teaching on students' academic motivation and their involvement as well as in their academic success. However, teachers, although they realize the importance of creativity, do not always know how to set up workshops or how to transmit this skill in connection with the academic skills usually taught. For example, Yates and Twigg (2017) propose a module for future teachers to encourage them in practical creative activities to develop their own creative skill and self-confidence. At the end of the module, students improve their knowledge on creativity and recognize, to develop children's creativity, the importance of proposing various activities and resources. In the same vein, Murray Or and Mitton Kukner (2015) propose a module called "literacy in the content areas" and highlight the more creativity-oriented teaching of these pre-service teachers. So Yates and Twigg (2017), like Murray Or and Mitton Kukner (2015), emphasize the importance of first practicing creativity to help teachers apply creativity in various activities with students. This education in creativity is very valuable as Karwowski et al. (2015) have shown that teachers' representations of their students' creative performance have an influence on creative self-efficacy as well as their sense of personal literary and mathematical effectiveness.

Effect of Pedagogy or Training Workshops

A first objective of this "mini" longitudinal research (a repeated measure study over a short-term period) is to examine the effect of pedagogical practices, whether permanent or more punctual. For example, research has shown the positive effect of alternative pedagogies on children's creative skills compared to traditional pedagogies (e.g. Besançon and Lubart, 2008). However, these results are not always favorable to alternative pedagogy, it may also depend on the type of task proposed or students' gender. More punctually, programs can be implemented over a shorter period of time. These programs are varied, such as the "Creativity Compass" program or the "learn to think" program which promotes scientific creativity. These programs are multi-month, even year-long, and the results show an improvement in creative skills (see the OECD study, Vincent-Lancrin et al. 2019), with these effects being found sometimes even a few years later (Hu et al., 2013). Some programs are short, taking place over a few weeks, showing a variety of effects (e.g., enhanced group work, reduced likelihood of leaving school earlier).

Research on students and young adults focused on the effect of different variables (such as creative self-efficacy, divergent thinking, creative intention, leadership, course satisfaction, group's norm) on creative performance in university teaching (e.g. Byrge and Tang, 2015). The results show that cognitive and emotional variables mediate the effects of contextual (e.g. course satisfaction, Choi, 2004a; 2004b) and individual (such as creative self-efficacy or creative intention, Byrge and Tang, 2015; Choi, 2004a, 2004b, 2012; Lim and Choi, 2009) variables on creative performance.

Other research has focused on the impact of various kinds of workshops on creative performance. This is the case, for example, with research, conducted by Gaggioli et al. (2015), in which teaching media psychology revealed an effect on collaboration, flow and creativity. Moreover, other research has focused on relaxation or meditation (Ding et al., 2015); results show an effect of meditation on creative performance of participants who practice meditation, which is not the case for those practicing relaxation.

Ma (2006) performed a meta-analysis of the effects of different types of training (e.g.: ideation, brainstorming, incubation, forced relation, catalog, improvisation, morphological synthesis, attitude, Syntectics, computer help, divergent-thinking-based programs). The results of this meta-analysis show a significant effect of training and it appears that training programs are more effective with young adult participants than with children and adolescents. The success of creativity training can be attributed to the development of cognitive skills such as strategies or thinking with a heuristic method.

In this kind of research, which deals with the effects of pedagogical practices, we observed that the use of a control group is not always present. Different control groups may be considered (1) an experimental group with the pedagogic practice that

the researchers wish to evaluate; (2) a group with the implementation of another teaching practice that should not have any effect on the development of creative performances and (3) a group where nothing is proposed. Thus, there should be significant differences in the development of creative performances between the creativity-focused treatment and each of these three groups.

Conclusion

Longitudinal studies provide important insights into the evolution of creative potential and creative achievements of participants. It is noteworthy that longitudinal studies take into account the different “dimensions” of creativity: from everyday creativity to eminent creativity. So far, most of the research has focused on either the development of creative potential in everyday life or the creative achievements of eminent people. An objective for future research will be to check whether the creative potential observed in everyday life at school or at home can determine creative achievements in professional life.

In recent years, researchers have developed new tools to assess creative potential (e.g. divergent thinking, convergent thinking, insight problems), creative personality or creative environment in which people evolve. One perspective of longitudinal studies is to verify that self-administered questionnaires predict participants’ creative achievements: does self-perception correspond to the potential that people express? The concurrent validity and predictive validity of creativity measurement tools remain to be demonstrated in longitudinal research. Second, creativity is multidetermined, so it seems essential to verify the impact of different factors on creative achievements of individuals. It should be noted that early research focused particularly on the creative person: concerning personality characteristics, studies have yet to demonstrate the effects of affects. Another point is to investigate each of the factors at different times in individuals’ lives. For example, does the environment in which the individual evolves have an equivalent influence at various developmental moments in a person’s career? The same question could be investigated for conative or emotional or cognitive characteristics.

Moreover, concerning methodological issues, recent advances in statistical analyses make it possible to have a more precise indication of the evolution of competences taking into consideration repeated measures and correlated errors. To date, longitudinal research have focused mainly on the study of inter-individual variability but work is needed on developmental profiles of creative potential that lead to accomplishments, taking into account the greatest number of explanatory factors (cognitive, conative and environmental). To go further, future research may focus on intra-individual variability over time looking, for example, about how emotions influence the creative process.

The Mad Genius controversy has been the source of curiosity for centuries, creating a type of accessibility to eminent creativity typically thought of as a preserved icon. References throughout history have highlighted the belief that there can be no great genius without a touch of madness, as illustrated in the creative works of famous documented emotionally disturbed writers, poets, artists, philosophers, and scientists including Franz Kafka, Edward Munch, Ernest Hemingway, Sylvia Plath, Fyodor Dostoyevsky, Ezra Pound, Vincent Van Gogh as well as others widely cited in the literature. While literary accounts and oral histories present anecdotal connections between creativity and madness of creatively gifted individuals who were often plagued with emotional and intellectual challenges, what evidence exists to document a link between creativity and madness? What primary disciplinary approaches can be used to understand this link? And further, what does this association suggest for related research, and our understanding of creative people? The current entry aims to address these questions by presenting research approaches and examples to contribute to an increased understanding of the connection between creativity and madness. The entry begins with a brief history of the mad genius controversy, followed by research approaches and examples that have been used to study this link, an analysis of theoretical interpretations, and concludes with implications for the treatment of psychopathology.

A Brief History of the Mad Genius Controversy

A common belief held for centuries is that madness is linked with creative thinking. [Rothenberg \(1990\)](#) describes this thinking and corresponding behavior as, "Deviant behavior, whether in the form of eccentricity or worse, is not only associated with persons of genius or high-level creativity, but it is frequently expected of them (p.149)." Since the time of the Greek philosophers, writings about the creative process emphasized that creativity involves reverting to more primitive mental processes, that to be creative requires a willingness and ability to cross and recross the lines between rational and irrational thought.

This idea of a mad genius, while providing a level of insight into the origins of the exceptional talent, may also neutralize all envy of their abilities through the solace of not having their talent, but also not their problems. Perhaps the greatest consequence is when those who have been diagnosed with serious disorders and are truly in need of treatment, do not seek it for fear of diminishing their gifts ([Piirto, 2004](#); [Berlin, 2008](#)), or "dampening" [their] general intellect and limiting [their] emotional and perceptual range" ([Jamison, 2006a](#), p. 20).

Another perspective offered by historical accounts suggest that a touch of madness was the romanticized notion of what was required in order to be creative, causing playwrights, poets, and composers to identify with the stereotype of the mad genius, and display evidence of these symptoms as part of this persona. According to [Becker \(2011\)](#), the existentialist philosopher Jaspers believed that the greater manifestation of mental illness in geniuses was "the result of society's selective granting of fame (p.74)." In other words, for Jaspers, genius was a label applied socially to talented individuals who displayed signs of a kind of madness. Becker's interpretation of Jaspers' belief was that the concept of mad genius was not applicable to all historical periods; rather the distinguishing characteristic between the 19th and 20th centuries versus the 17th and eighteenth. Becker's interpretation further posited that it was the general mood or inclination in Western society that "craves the mysterious, the unusual, the undefinable, and the blatantly diseased (p.74)." The idea of these "unusual" representations of thought interpreted by many as creativity speaks to results of various studies and anecdotal reports suggesting an increased rate of schizophrenia, manic-depressive disorder, depression, personality

disorder or alcoholism among creative individuals. As Ludwig (1995) points out, it is also important to consider ways in which different types of emotional disturbances impact creativity expression. Depression, for instance, may decrease verbal associations, constrict coloration, encourage nihilism and sadness, shift focus from living to dying, and reduce work production. Mania may affect the rate, flow, and cadence of speech, increase prolixity and word play, produce disjointed and tangential thought, give rise to expansiveness and grandiosity, and foster prolific output or productivity. Schizophrenia may contribute to disorganization and incoherence in writing, musical composition, or painting, or provide the inflexibility of delusional convictions. Conservative amounts of alcohol and drugs may decrease inhibitions and performance anxiety, while increasing confidence, or offering new visions of reality; in excess, these substances may lead to muted, garbled, or nonsensical presentations of ideas and a decline in productivity and execution.

While it is quite clear that emotional instability is usually detrimental to creativity, it also may be advantageous. It may provide the intense focus, motivation, the conviction, egocentrism, the unconventionality, the imagination and the inspiration so necessary for new discoveries and breakthroughs. It may also allow the artist, writer, poet, composer and scientist to escape the powerful social and cultural constraints that mostly favor ease, conformity and convention.

Another lens through which to view this controversy is that of professional considerations which suggest that the creative arts attract certain types of individuals, and that expectations also determine whether or not they reveal any emotional difficulties. In addition, as Ludwig (1995) points out, individuals in the creative arts often flaunt their emotional instability as a badge of honor, receiving accolades, increased tolerance or understanding from others, while in other professions like the military or science, individuals hide their instability for fear of repercussions to careers and reputations.

Research Approaches to Studying the Link Between Creativity and Madness

Attributions of madness responsible for creative activity have often stemmed from such stories as Van Gogh's mutilation of his own ear and Truman Capote's alcoholism, fueling the popular belief that madness and creativity go hand in hand. However, researchers have also explored this controversy from three main perspectives, historiometric, psychometric, and psychiatric in an attempt to uncover patterns and determine trends.

The historiometric approach quantitatively analyzes historic data. Specifically, the biographies of eminent creators are systematically evaluated to identify the presence of symptoms associated with various psychopathological syndromes. For example, using this approach, Simonton (1994) examined 291 famous men in a study designed to determine the prevalence of various psychopathologies to test the hypothesis that the high incidence of mental abnormalities described in prominent living creative individuals would not be found in those who had achieved and maintained world status. Examinations of family background, physical and mental health, psychosexuality and personality of famous men in science, politics, thought, and art were investigated. The disciplines of these men included scientists and inventors, thinkers and scholars, statesmen and national leaders, painters and sculptors, composers, novelists and playwrights. Extracted data were coded according to DSM-III-R criteria where appropriate. Results of the investigation demonstrated that all these men excelled both due to their abilities and originality, as well as their drive, perseverance, and meticulousness. Their biographies revealed, with few exceptions, that they were all emotionally warm, sociable and friendly individuals. Simonton found that most of these men had unusual personality characteristics and that their minor "neurotic" abnormalities were more common than what was seen in the general population. Visual artists and writers in this sample had the most severe personality deviations, with functional psychoses restricted to the affective varieties, occurring less frequently than psychiatric epidemiology would anticipate. Results also indicated that among other functional psychiatric disorders, only depressive conditions and alcoholism were considerably prevalent in writers. In a more recent study, again using the historiometric approach, Simonton (2014) studied 204 eminent scientists, thinkers, writers, artists, and composers. Results revealed that scientists display the least psychopathology and the thinkers the most, with the composers falling approximately in the middle. As these studies illustrate, the historiometric approach yields the following three conclusions: First, among eminent creators, psychopathological symptoms appear to occur at a higher rate than in the general population (Simonton, 1994; Raskin, 1936). Depression appears to be the most common symptom often correlated with alcohol use and alcoholism (Ludwig, 1990; Post, 1996). Second, the more eminent the creator the more intense the psychopathology (Ludwig, 1998), and third, psychopathology is higher among artistic creators than those in the scientific domain (Post, 1994), indicating that the rate and intensity of symptoms varies according to the specific domain of creativity (Goertzel et al., 1978; Raskin, 1996; Post, 1994).

The psychometric approach applies standard assessment instruments (e.g., the Minnesota Multiphasic Personality Inventory (MMPI) and the Eysenck Personality Questionnaire (EPQ)) to contemporary creators (Gough, 1953). For example, Acar and Runco (2014) conducted a meta-analysis of 32 studies on the topic and found that when psychoticism was measured by the EPQ, the relationship between creativity and psychoticism was large ($r = 0.50$, 95% CI[0.39, 0.60]), indicating that the relationship between creativity and psychopathology appears to have an intermittent and specific relationship; rather than a broad and more general one. Acar and Runco (2014) go on to suggest that perhaps the fame and presence of psychoticism itself has an impact on what attracts fame and earns eminence. They further posit that a related possibility is that perhaps fame leads to a collection of detailed information in the form of biographies and autobiographies, which in turn allows easier interpretation of psychopathology. A key point they make is in the example of Isaac Newton, rumored to have autism. However, this rumor only started after autism was defined in the 1940s, during which time it was recognized as a legitimate diagnostic category for mental health professionals. After the definition of autism was made public, biographers could easily retrace Newton's idiosyncrasies, only because Newton was famous, and much had been written about him.

The psychiatric approach depends on clinical diagnoses and therapeutic treatments in contemporary creators. In the last two decades, a number of studies have examined the connections between creativity and madness from the psychiatric perspective, including works by [Rothenberg \(1990\)](#) and [Jamison \(1993\)](#). Observations from psychiatric studies identify three characteristics common to both high creative productivity and madness: disturbance of mood, certain types of thinking processes, and tolerance for irrationality.

In the genre of visual arts, disturbance of mood appears to be present in a high percentage of talented artists ([Jamison, 1989](#); [Richards, 1981](#)). According to [Neihart \(1998\)](#), mental disorders in which the primary feature is a mood disturbance include major depression, bipolar disorder (also known as manic-depressive illness), and dysthymia. In eminently creative people, especially writers and artists, there seems to be a greatly increased rate of depression and manic-depressive illness. The incidence of mental illness among creative artists is higher than in the general population. Some studies have linked creativity with bipolar disorders specifically ([Jamison, 1989](#); [Richards, 1989](#)), and within the field of academic psychiatry, there has recently been acceptance of the association between creativity and the mood disturbance, hypomania ([Jamison, 1993](#)).

The effect of moods on personality has been well-documented. Bipolar disorder is one example characterized as a recurrent mood disturbance typically manifesting as cyclical, extreme mood swings that include manic states. The manic state is a distinct period (around one week) during which an individual exhibits a euphoric high or irritable mood. The extreme poles are described by the [American Psychiatric Association \(1994\)](#) as, "The expansive quality of the mood is characterized by unceasing and indiscriminate enthusiasm for interpersonal, sexual, or occupational interactions (p. 328)." Grandiosity or inflated self-confidence is frequently observed. During a state of mania, thoughts race, often at a speed faster than can be articulated. There is an intensive increase in goal-directed activity, during which time manic individuals may paint numerous works, write volumes, or participate in multiple activities simultaneously. The intensity and level of activity may be so high that it results in functional impairment, with the possible need for hospitalization to protect the individual. Creative productivity is often preceded by elevated mood. [Jamison \(1993\)](#) suggests that certain moods appear to open up thought allowing for greater creativity, and that depression may have an important cognitive influence on the creative process by slowing the pace, putting thoughts and feelings into perspective and eliminating irrelevant ideas, heightening focus, and allowing the framework of new ideas to emerge. These observations suggest that perhaps the link between creativity and madness are the cognitive processes associated with certain moods.

One of the most interesting findings from the clinical literature are the documented similarities in the thought processes of psychotic, manic, and highly creative individuals ([Prentky, 1980](#); [Rothenberg, 1990](#); [Rothenberg and Burkhardt, 1984](#)). While it is rare for psychotic thinking to turn into creative production without some reduction of the psychosis, there is evidence that creative processes sometimes turn into psychotic ones ([Niehart, 1998](#)).

The comparisons of the three research methods reveal similarities of findings from the historiometric and psychiatric studies where symptoms found among eminently creative individuals are analyzed according to each field of study. The historiometric approach quantitatively analyzes historic data and focuses on symptoms found in biographies, which is the unique angle of this approach. Psychiatric studies also examine traits, diagnoses, and clinical perspectives of how creativity manifests in these individuals and at what cost or benefit to their mental health. The psychometric approach depends on clinical diagnoses also provided in psychiatric studies; but is unique in that it stresses the relationship between creativity and psychoticism as measured by standardized assessments. Each approach provides a unique perspective on what drives eminently creative individuals to produce at such high levels.

Theoretical Interpretations of Historiometric, Psychometric, and Psychiatric Research Approaches

What then is the actual relationship between creativity and madness? The interpretation of these research approaches and studies demonstrate that creativity shares common cognitive and dispositional traits with specific psychopathological symptoms, and that the way these commonalities manifest is dependent on the level and type of creativity displayed by the individual, which can be influenced by a number of factors including historical context and family dynamics. Specifically, evidence suggests that in order to be creative, novel, unconventional, and unexpected approaches combined with a willingness to explore such possibilities need to exist. Creators must be open to serendipity using such traits as divergent thinking, defocused attention, an openness and independence of thought, which together form a constellation of traits.

The greater the level of creativity displayed, the higher the likelihood that the individual manifests this constellation. In addition, some domains require this constellation more than others do. For instance, scientific creativity tends to be more reliant on logic and fact than artistic creativity. Thus, this creativity constellation of attributes will be more apparent in artists than in scientists ([Simonton, 2004](#)). However, differences will exist even within these general domains. For example, artists creating in a more classical, formal style will operate under more constraints than artists working in more expressive, romantic, or subjective styles ([Ludwig, 1998](#)).

Creativity can be said to be biologically determined to the extent that these symptoms have a genetic foundation. And though cognitive and dispositional traits are seen in psychopathological symptoms, many environments and circumstances provide conditions for the growth and development of these traits. For example, connections are often made between creative development and traumatic experiences in childhood or adolescence, experiences that may also contribute to depression and suicidal tendencies ([Goertzel and Goertzel, 1962](#)). While on the other hand, development of these traits are also linked to a rich, diverse, and stimulating intellectual and cultural environment, one that is neutral with respect to psychopathology ([Simonton, 1999](#)). Growing up in

the midst of such conditions nurtures the emergence of many cognitive and dispositional traits that define the creativity constellation of traits.

Implications for the Treatment of Psychopathology

The theoretical interpretations outlined previously indicate that creativity and psychopathology share a set of traits, and that the frequency and intensity of how these traits are expressed are dependent on the magnitude and domain of creative achievement. This explains why we see highly creative individuals manifest psychopathological traits. In addition, the disinhibition and overinclusiveness that may accompany some psychopathological states may give rise to unusual pairings of thoughts or ideas, which to the general public, may be considered highly unusual, novel, and creative, though they may not meet the definition of creativity as involving both novelty and usefulness. Though these symptoms may be at subclinical levels, they are also tempered by positive traits like ego strength, persistence, and forthrightness, which can be nurtured by environmental factors that lessen their tendency toward psychopathological states.

These concepts together suggest that creativity is not entirely inconsistent with mental and emotional health, supporting many cases of creative individuals who display little to no symptoms. For this reason, creative individuals should feel no hesitation to get the help they may need to assuage psychopathological symptoms as they appear for fear that their creative abilities will slip away. Treatment could, in part, focus on strengthening the positive traits like ego strength, and openness to experiences that have a positive relationship with creativity and mental health. Clinicians have taken an oath to be informed about the diseases they treat, and to recognize the importance of medication even if the individual rejects it. Some individuals can become addicted to mania—"as a drug, hypomania leaves cocaine in the dust (Jamison, 2005)"—romanticizing their illness and attempting to recapture their highs by any means possible. But the risks of refusing medication are higher than any creative loss that may occur, as seen in findings that demonstrate that patients on lithium are nine times less likely to commit suicide. In fact, even the loss of one's creativity should not be a great worry; two-thirds of patients report no change in intellectual ability and three-fourths no decline in productivity (Jamison, 1993).

Conclusion

The mad genius controversy is a polarizing and divisive issue in the field of creativity research but with the psychometric, psychiatric, and historiometric evidence reviewed here, it is likely that psychopathology and creativity are closely related; sharing many traits and antecedents while outright psychopathology may be negatively associated with creativity. Therefore, individuals with full-blown schizophrenia or alcohol dependence may not be demonstrating creative ability; rather only milder forms of these mental illnesses may be conducive to some forms of creativity. Family members of psychiatric patients may display higher levels of creativity, findings that are consistent in studies across all psychiatric disorders. While many creative individuals may feel stigmatized and ignore their psychopathological symptoms for fear of losing their creative ability, it is important to treat them to prevent adverse outcomes and overall reduction in their creativity during their lifespan. The poet, Kahlil Gibran (1918), beautifully captures his own connection with the mad genius controversy in these words, "I have found both freedom and safety in my madness; the freedom of loneliness and the safety from being understood, for those who understand us enslave something in us."

An Overview of the History of Magic

Magic, also called conjuring, aims at entertaining the audience with counterfactual illusions, such as making objects disappear or suspending them in the air. The person who performs the magic is referred to as a magician or conjuror. Historically, people's views toward magic have varied, which is reflected by the terms used to describe magic, such as illusions, tricks, black magic, supernatural power, and scientific spectacles. Accordingly, the magician's role has also changed throughout history and has included entertainer, showman, witch, trickster, and scientist.

The first historical record of magic is from 1700 BCE Egypt in the book known today as *Westcar Papyrus* (Blackstone and Reynolds, 1985). This book described a magician named Dedil, who performed magic for Cheops, the Pharaoh who built the pyramids. Other historical records also indicate that magic was performed in ancient Greece and Rome. For instance, Hero of Alexandria, the Greek engineer and physicist, who lived around CE 62, designed various mechanical devices for the temples. Those devices enabled him to perform magical divine phenomena to enhance the religious belief of worshipers. Some early magic records have also been found in Asian locations such as China and India. When Marco Polo (late 13th century) travelled to Asia, he described in his book *The Travels of Marco Polo* that Chinese conjurors could prevent rains and caused thunder and lightning (Blackstone, 1985). Polo reported that these Chinese performers performed solely for entertainment purpose at that time.

Although some audience members did regard magic performances as illusions and viewed conjurors as magic-entertainers or jugglers, some royal members of the audience may have interpreted the sleights of hand as displays of supernatural and occult powers. In early centuries, people even described magic performance as "black magic", and early Christianity regarded magic performances as pagan practices. Augustine (CE 354–430), in *City of God*, described magicians as men who used demonic arts. *The Discovery of Witchcraft*, written by Reginald Scot in 1584, aimed to dispel the myth of the supernatural power of magicians and exposed them as conjurors' tricks. Thus, magicians have played roles throughout history, including entertainer, trickster, and witch.

In the mid-eighteenth century, some magicians in Europe began to adopt the fruits of the industrial revolution—the latest scientific technology—in their performances. Thus, they played a new role as science demonstrators. For instance, Maillard demonstrated his artificial magical swan that could mimic the behavior of a natural swan in 1733. Starting in 1735, Jean-Antoine Nollet utilized electricity to produce his special effects, such as transmission of electric shocks to a group of people holding hands. These scientific magic shows occurred in small scientific fairs. When theaters began to appear in late 19th century America and England, magicians seized this opportunity and moved their shows from the street and scientific fairs to theaters. Nowadays, the main purpose of magic is still entertainment, but we also have witnessed several innovative uses of magic in fields such as education, therapy, neuroscience, and psychology.

The Innovative Use of Magic in Different Fields

Science Education. In recent years, magic has become a pedagogical tool for science educators to raise students' motivation in science education. There are two reasons for this: 1) the seemingly impossible magical effects always raise students' curiosity about the secrets of the magic; 2) some magic is based on scientific principles and knowledge. Therefore, some creative science educators use magic performance as a discrepant event stimulus to engage students in the scientific inquiry process with the goal of uncovering the science behind the magic. For example, *Brain Powered Science – Learning with Discrepant Events*, written by Thomas O'Brien (2010), is a science magic encyclopedia covering various types of science magic tricks and related pedagogical strategies to teach

chemistry and physics. In this book, he suggested that the unexpected outcomes demonstrated by magic challenged students' pre-conceived ideas and motivated them to examine their assumptions with empirical data and draw new scientific conclusions. His argument was also supported by the increasing number of empirical studies in science education research.

Therapeutic tools. Magic has also been used as a therapeutic tool to help students with disability or learning challenges. Since performing magic requires a high motor object manipulating skill, engaging students with motor disabilities in learning magic can improve their motor ability. The Project Magic program, established by the world famous magician David Copperfield, aims at teaching therapists how to use magic tricks as a form of therapy for improving patients' motor skills. A similar program, Hocus Focus, developed by Kevin Spencer, teaches individuals with disabilities magic tricks. Besides improving skills, both programs emphasize the positive influences of performing magic on individuals' self-esteem and communication skills. This is because magic enables individuals to create "miracles" that their non-disabled peers cannot achieve and thus gives performers a sense of achievement.

Neuroscience Psychologists testing tools. The magic props and mechanics developed by magicians is not the only reasons why magic is achieved. The main reason is that magicians know how to take advantage of the limitation of people's attention and perception. Magicians developed principles of misdirecting people's attention to hide the method and persuade the audience to believe in the reality of the magic effects. Those principles caught the attention of psychologists and neuro-scientists, who adopted magic tricks as an experimental tool to study visual attention, insight problem solving and memory distortions. To help psychologists use magic to conduct scientific study, [Rensink and Kuhn \(2015\)](#) developed a framework outlining how magic could be fully exploited to understand the human mind from four different levels: methods in magic, the effects of magic, the combination of effects and magic, and the experience of wonder.

While magic has been used in different fields for different purposes, the potential of magic has not been fully tapped. An increasing number of studies suggesting the connections between magic and creativity have begun to emerge. Before introducing how magic has been used as a tool for facilitating creativity, it is necessary to discuss these studies to understand why magic can be used to facilitate creativity.

Cognitive Dissonance

The effects brought about by magicians present a reality that differs from people's expectations. These effects create a magical experience that elicits a cognitive dissonance in the minds of audience members. The cognitive dissonance might disturb people's implicit beliefs about impossibility and possibility in the world, which might encourage them to think beyond the realistic world and thus enhance imagination. This special experience elicited by magic has been studied in the neuroscience, psychology, and social science fields, which establishes a foundation for using magic to facilitate creativity.

Recent neuroscience studies identified the brain areas influenced by the magic watching experience, which confirmed that magic performance is more effective in eliciting cognitive dissonance than other stimuli. For instance, [Parris et al. \(2009\)](#) used an MRI machine to investigate brain activity while watching a magic performance. Their results suggested that compared to other surprising stimuli, magic is more effective in activating the dorso-lateral prefrontal cortex (DLPFC) and the anterior cingulate cortex (ACC). The ACC is the area of the brain that mediates cognitive dissonance and controls the perception of causality. The ACC is activated when the brain is confronted with inconsistent information, such as impossible events. An example of this kind of event is a performance of the "suspended ball" trick. In this trick, a magician throws a ball into the air, where it remains suspended. When the ball is thrown into the air, the audience likely assumes that the ball will fall back down, according to their experiences. After seeing the ball suspended in the air, an alternative reality brought about by the magic disturbs the causal relationships learned through previous experience and knowledge, which activates the ACC. It is worth noting that ACC is related to people's cognitive flexibility, meaning that magic performance could be used as a stimulus to activate the ACC and further enhance creativity. However, no neuro-science study to date has directly tested such a connection.

On the other hand, research in social science studies indicated the connection between cognitive dissonance and divergent thinking, which indirectly provides evidence for the magic-creativity connection. For instance, [Ritter et al. \(2014\)](#) investigated the influence of cognitive dissonance on people's thinking flexibility. Specifically, they asked the participants to watch a film scenario that violates traditional thinking, and they found that those who watched the film scored higher on Guilford's Unusual Uses Task than those who did not.

This result was also supported by several cognitive studies. For instance, [Gołowska et al. \(2013\)](#) reported that individuals tended to generate more creative ideas when their mind were disturbed by counter-stereotypical social examples (such as a hippy-lawyer, a woman-rugby player). [Galinsky and Moskowitz \(2000\)](#) also showed that individuals who encountered a counter-factual mindset attenuated their confirmatory bias and generated more creative solutions to a problem. Although these social science studies did not use magic directly in their experiments, all of the stimuli used by them aimed at eliciting a cognitive dissonance in individuals' minds, and the results suggested a positive influence of cognitive dissonance on thinking flexibility. This implies that magic performance can facilitate creativity as magic is more effective at eliciting cognitive dissonance than other stimuli. However, these studies did not further investigate the underlying cognitive mechanism and explain why cognitive dissonance can lead to creativity. Therefore, to clarify this mechanism, the following section introduces magical thinking, an important concept that helps understand the underlying cognitive processes.

Magical Thinking

The term *magical thinking* varies by field. In psychology, magical thinking is generally used to describe people's belief that their thoughts, wishes or desires can influence the external world. Magical thinking has also been used in psychiatry to describe mental health disorders such as schizophrenia and obsessive compulsive disorder.

In this chapter, Subbotsky et al. (2010)'s definition of magical thinking is used to illustrate the connection between magic performance and creativity because of its emphasis on imagination. Subbotsky et al. (2010) defined magical thinking as the ability of individuals to construct an alternative world using their imaginations. In his book *Magic and the Mind* (2010), Subbotsky made a clear distinction between magical thinking and magical belief: magical thinking is related to imagination, whereas magic belief refers to an individual's belief that magical events may exist in reality and impact the real world. For instance, imagining Harry Potter or his magical power does not require believing either that Harry Potter exists or that his power could have a real impact in actuality. It is also worth noting that magical thinking differs from ordinary imagination in that it must involve violations of known physical principles. For instance, imagining flying with a broomstick like Harry Potter belongs to magical thinking, whereas imagining having a fancy car does not. In addition, children and adults differ in levels of magical thinking. As a child grows up, the magical view of this world is gradually replaced by realistic causal explanations. Compared to adults, children's fantasy and imagination are "stronger and richer because of the greater excitability of feeling, the intensiveness of experience, and uncritical judgement" (Vygotsky, 1991, p. 82). In other words, children's ideas are more original because they think less about reality and rely more on their own feelings and magical thinking.

The relationships among magical experience, magical thinking, and creativity have been investigated by a series of studies conducted by Eugene Subbotsky. One of his studies (2010) suggested that children who watched magical films (such as the *Harry Potter* series) significantly scored higher on originality on the Torrance Test than children who did not. He concluded that watching magical content encouraged participants to use their magical thinking and develop novel and counterfactual solutions to a problem.

A recent study conducted by Tong (2018a) further confirmed this. In this study, magic performance was used as a stimulus to facilitate thinking flexibility in an undergraduate class. Participants not only watched magic performance in class but also were taught to perform magic and learned the magic principles. The results suggested that participants' divergent thinking was significantly increased after the intervention. Furthermore, this study also clarified how magic influences people's magical thinking at different cognitive levels. The main influence is caused by the priming effect. Priming refers to a temporary activation of certain thinking that influences people's responses to tasks that follow. When participants had magical experience by either watching or performing magic tricks, they were primed with a magical thinking process. Once magical thinking was activated, participants were more likely to apply this thinking process to other activities and to come up with alternative ideas. Additionally, magic can also influence people's thinking at the reflective level. In Tong's study, participants not only watched magic performance but also learned how magical thinking benefits magicians and enabled them to develop creative magic ideas. Thus, they understood the value of magical thinking and became more willing to make changes and take actions toward the direction indicated by it.

The underlying mechanism revealed by studies mentioned above provides a theoretical support for the efforts made by practitioners in exploring the use of magic to facilitate creativity in design and science fields. These practitioners used magic and magical thinking to reduce cognitive fixation and inspire creativity in various ways, which will be introduced in the following sections.

Magic and Creativity in Design

In the design field, design fixation becomes a barrier for designers in finding and developing effective and creative solutions, especially during the ideation phase of design thinking. One method to reduce fixation is temporarily ignoring realistic constraints and imagining the possibilities and alternatives. Magic has been used to help designers escape those constraints and generate novel design ideas. For instance, Al'tshuller (1999) proposed a method for reducing designers' fixation by asking them to imagine that they were given a magic wand and they had the magic power to solve the design problem. The designers needed to think of idealized magical solutions so as to increase the uniqueness of their design idea. He suggested that using this method maximizes the imaginations of the designers and improves their design creativity. Similarly, Stanford professor John Arnold (2016) asked designers to imagine they were on a magical planet called Arktur IV to solve design problems. In both cases, magic was used to create a novel design space for designers. The magical design space elicited cognitive dissonances in designers and stimulate their magical thinking. The magical thinking mindset activated encourages designers to make unusual combination of different thoughts and ideas that cannot be achieved within a design environment full of rigid constraints.

In addition to using magic to create a magical design space, a few design researchers focused on the value of magic effects and the magic experience created by magicians to enhance the magical thinking of designers. For instance, Watson et al. (2014) proposed using stage magic effects (such as vanishing, levitation, etc.) to help designers develop creative products that can provide magical experiences to their users.

They translated the meaning of these magical effects into design elements that could be adopted by designers. For instance, the magic effect "levitation" means designing a product that can rise or hover by itself. Designers were encouraged to think of methods that enabled the products they designed suspend in the air. The study suggested that products embedded with such magical elements were more innovative and more preferred by the target users.

In another study, Busk et al. (2012) proposed a conceptual framework to inform product designers how to create a magical experience like a magician to improve user experience. The framework divides the magical experience into internal and external magical experience, depending on whether the user has control over the magic power. They suggested that designers should practice thinking about magic and consider how their design products could facilitate both types of magical experience so as to provide a pleasurable feeling for their users. In addition, there are design practitioners whose design practice directly benefits from magic performance and magical thinking. For instance, in England, designer Adrian Westaway adopted the principles he learned from magic in his design practice. He established Special Projects (<http://specialprojects.studio>), a design company that provides magical design solutions. In his TED talk, he shared the story of how being a magician inspires him to come up creative design ideas. His magic performing experiences encouraged him to consider improving the “magical feeling” of his design products.

Besides the use of magic effects and principles to improve magical thinking of designers and the uniqueness of their design products, the magic creating process of magicians also drew attention of design researchers. As suggested by a designer (Tognazzini, 1993), the development of a magic performance is similar to that of a user-centered digital product in that both try to create a virtual reality or magical experience based on the psychological understanding of human nature. Inspired by this, Tong (2018b) used the magic creating process of magicians to guide students’ product design process, in which students learned magic and the design principles from a magician and applied the principles to their design projects. The results showed that magic learning performance increased students’ empathy for their target audience and also enhanced their creativity. This study demonstrated a new approach to using magic to facilitate creativity—encouraging people to perform magic so that they can form a deeper understanding of the principles of magic. For instance, as a magician, in order to successfully trick the audience, it is necessary to think from the perspectives of the audience and refine the magic accordingly. Such magic performing experience might help people focus less on their own ideas and care more about the suggestions given by others, which might reduce their fixation and improve thinking flexibility.

Magic and Creativity in Science

As quantum physics emerges, the line between magic and science is becoming blurred. Some seemingly impossible magical effects become true in the quantum world. This requires scientists to not only rely on the traditional scientific reasoning but also on their magical thinking to envision the new possibilities. Österblom et al. (2015) used the fact that magicians trick their audiences as a metaphor to remind scientists not to be tricked by perceived experiences and realities. He suggested that scientists should think like magicians to challenge the perceived reality and explore this world with their imaginations. Previous research also suggested that such an imaginative mindset is crucial for scientist to make great scientific breakthroughs. For instance, studies of Nobel Prize and MacArthur Genius award winners indicated that their scientific contributions were connected to their early experiences with artistic practices (Root-Bernstein and Root-Bernstein, 2006). The imaginary experiences they received in the artistic activity enabled those award winners to conduct similar imaginary play in the scientific world.

Like magicians who try to break the realistic law with their imagination and are driven by unexpected magical events, those scientists who made scientific breakthroughs are aiming for expanding scientific knowledge with their imagination and searching for surprises and anomalies. For instance, Alexander Fleming, the British bacteriologist known for the discovery of penicillin, was also famous for his love of painting with germs. Although he was not an artist, his painting provided an imaginary space for him to play freely with living bacteria. To paint his pictures, he formed a familiarity with his “friend”— knowing which microbes produce which color and the timing of their growth rates. Most importantly, such special intimacy enabled Fleming to see through biological phenomenon and sense the unexpected patterns and outcomes. Fleming’s discovery of penicillin was a manifestation of his ability to envision new possibilities. If he had never imagined the possibility that mold could benefit human beings, we would not have penicillin to use today. Similarly, the virologist Jonas Salk, who discovered polio vaccine, said in his book *Anatomy of Reality*,

I would picture myself as a virus, or as a cancer cell, for example, and try to sense what it would be like to be either. I would also imagine myself as the immune system. I soon found myself in a dialogue with nature using viruses, immune systems ...

Magical thinking enabled Salk to not only establish relationships with the unfolding nature of mystery but also look at the problems in new perspectives. This increased his chances of discovering serendipity that lead to the next scientific breakthrough.

Interestingly, in the history of magic, many magicians were also great inventors. For instance, Hero of Alexandria, mentioned earlier, is believed to be the first person to invent a vending machine. Unlike the vending machines used today for simplifying people’s lives, Hero’s machine was built to demonstrate this automation miracle and enhance the magic belief of the temple followers. Georges Méliès (1861–1938), a French stage magician and film director, made the first fictional movies and invented the method of adding special effects to film. His magic performance experience and magical thinking inspired him to invent the tricks that changed movie history. Additionally, modern inventors also benefit from magic. For instance, Richard Garriott, an inventor, astronaut, and well known game designer who came up with the idea for the famous multiplayer online game *Ultima Online*, was inspired by his magic performing experience. In his book *Explore and Create*, he discussed how his early magic

performing experiences encouraged him to seek the real magic by becoming a game designer and adventurer. His experience inspired him to explore the unknown and believe that everything is possible.

Arthur C. Clarke, a well-known British science fiction writer, famously stated, “Any sufficiently advanced technology is indistinguishable from magic,” which suggests that technology inventors should think like magicians and believe that everything is possible. Magic thinking can encourage scientist or inventors to challenge traditional thinking and come up with ideas that can revolutionize the field. It is possible that performing magic can also encourage people to challenge traditional thinking and come up with great ideas.

Conclusion

Magicians devote their time and effort into creating wonder for audiences. This wonder- and magic-driven mindset might also benefit people in other fields in different ways. Watching magic performances may encourage people to expand their thinking and to change the existing world with their imaginations. The priming effect makes it possible to use magic to activate a counterfactual thinking mindset in people’s minds so as to enhance creativity. Additionally, through thousands of years of practice and development, magicians have developed their principles of creating magic that amazes their audiences. Those principles could be adopted by other fields that need to provide similar magical experiences, such as user experience design. It is worthwhile for educators to consider bringing magic into their classes and creating a magical environment for enhancing students’ creativity. And finally, thinking like a magician may encourage scientists and inventors to think beyond reality and explore the unknown world and thus bring about more scientific breakthroughs and inventions.

Glossary

Bisociation One view of creative cognition, proposed by Arthur Koestler. It focused on a synthesis of unconscious and conscious thought and the combination of disparate bits of knowledge.

Magic synthesis The description of creative thinking proposed by S. Arieti. It is also known as tertiary process because it involves a synthesis of primary process material with secondary process.

Primary process Thinking and feeling that is unconscious, instinctual, raw, uncensored, uncivilized. It is guided by the pleasure principle.

Secondary process Thinking and feeling that is guided by the reality principle and involves censoring and governing primary process such that behavior is civilized, mature, and conventional.

Tertiary process A synthesis of primary and secondary process which leads to creative cognition.

The term, *magic synthesis*, was coined by Arieti in 1976 in a book of that title. The term is not used all that often, but as this entry will demonstrate, it is a very useful concept that is implicit in quite a bit of the thinking about creativity, even when the term “magic synthesis” is itself not used. In fact recent neuroscientific and cognitive research suggests that the concept is becoming an increasingly important one. That research will be summarized below, after Arieti’s own ideas are reviewed.

Arieti based his theory of creativity as a magic synthesis after a close examination of art. This is interesting because Freud said that “psychoanalysis can do nothing toward elucidating the nature of the artistic gift, nor can it explain the means by which the artist works—artistic technique Freud (1958, quoted by Gilman, 1976, p. 173).” Arieti also drew heavily from his work as a clinician. Often it is unwise to generalize from uncontrolled research, including that which involves examination of art, and even more unwise to generalize from clinical samples. On the other hand, such work does have value in its depth and in that it can suggest hypotheses which can be later tested with controlled research. This is exactly what happened with Arieti’s ideas about a magic synthesis. Several empirical studies, mostly by Klaus Hoppe, tested Arieti’s ideas, and largely supported them.

Freud’s influence on the concept of a magic synthesis is obvious in that it depends entirely on primary and secondary process. Indeed, the magic synthesis is the creative result of an interplay of primary and secondary processes. They are usually quite distinct and for the most part incompatible, but some of the time, for some people, they can be synthesized, the result being creative. Arieti’s description of that synthesis is a proposal for a mechanism to explain the origin of creativity. To the degree that the concept of a magic synthesis holds up to rigorous experimental research, this is enormously important. Too often theories of creativity are merely descriptive and fail to include an actual mechanism. Without a mechanism, there is no real scientific explanation (Jay and Perkins, 1997; Runco, 2007).

Primary process is raw, uncensored, libidinal, or what Arieti calls *paleological*. The id is readily apparent in primary process, and in fact newborns feel and express the drives supplied by the id. Their ego and superego have not yet developed and thus cannot direct libidinal and instinctual drives towards socially acceptable, realistic, or ethical expression. Secondary process censors primary process material so the individual can act in a mature and conventional fashion.

This idea of censorship is quite important for explanations of creativity. Think, for example, about Rothenberg’s (1990) interviews with the Nobel Laureate John Cheever. These interviews showed how Cheever drew from primary process—but it scared the hell out of him, to paraphrase. Such fear often arises when an individual realizes that their thinking or feelings reflect some primary process. It can be embarrassing or scary. This is why, according to Freud, people so often employ defense mechanisms. These can protect the individual so he or she does not realize that there is a raw libido and instinctual drive at work. Some defense mechanisms rationalize or project primary process drives. Art is sometimes thought of as sublimated primary process, the idea being that the raw unconscious provides ideas which are surprising and perhaps even original (because convention and morals keep most people from seeing and expressing them). Self-censorship of primary process is very important for a civilized society, but when taken too far, self-expression and creativity are likely to suffer.

This is all very important because, in addition to the key idea is that creativity is a magic synthesis of primary and secondary processes, Arieti also offered an equally noteworthy idea about the connection between health and psychopathology. Health and psychopathology are not two ends of a continuum, for Arieti, but instead sometimes related. Simplifying, the logic here is that there are people who experience psychosis or some psychopathology because they use a defense mechanism inappropriately (by society's standards) or there is a severe imbalance in the psychic system. You might say that the interplay of primary and secondary processes is suboptimal. There is also the possibility of an adaptive interplay of primary process and secondary process. It may lead to creativity! The point is that psychopathology and psychological health are connected, not entirely distinct from one another. The same underlying dynamic is at work in both. They are not opposites.

This same idea about health and psychopathology is explicit in the work of Hans Eysenck and his theory of overinclusive thinking. According to Eysenck, creative ideas result from thinking where the individual includes things that are typically excluded. A creative idea might make sense, but most people do not think of it because it is actually outside of the conceptual category as defined by convention. The idea of a "brick" is, for instance, outside of the category of "round things." Yet an overinclusive process often includes things that do not typically belong, so an overinclusive person may think of brick. Much the process has been described with the label *loose associative boundaries*.

One result of overinclusive thinking is that a person may appear to be out of touch with reality (bricks are not round!), and at the extreme, may appear to suffer from a form of psychopathology, perhaps even psychosis. Other individuals may think in an overinclusive fashion but control and direct it, or at least only share the ideas that result when they are in the service of creative thinking. Note that one result is psychopathology, but the other is a creative capacity. Both depend on one process, which is quite consistent with Arieti's theory. For Eysenck the mechanism underlying health and psychopathology is overinclusive thinking, while for Arieti the mechanism involves an interplay of primary and secondary process.

Evidence

As noted above, Arieti's ideas about a magic synthesis were based on observations of art and clinical interviews; but there have been empirical efforts to test the idea. The role of primary process has been included in a large number of theories of creativity (Kris, 1952; Koestler, 1964; Martindale, 1990), and some have been experimentally tested. Martindale, for example, examined the primary process underpinnings of creative products several times. The most direct test of Arieti's idea of a magic synthesis—where both primary and secondary processes are involved—was that of Klaus Hoppe and Neville Kyle, reported in the 1990 *Creativity Research Journal*.

Hoppe and Kyle worked with the patients of Roger Sperry, who won a Nobel Prize for his work on the so-called "split brain." The technical term of the operation is a commissurotomy because it was the corpus callosum (the bridge between the two hemispheres) that was cut in the patients. They were indeed patients, each of whom suffered from severe epilepsy. Each had frequent grand mal seizures, and for that reason did not lead fulfilling lives. This was before medication could control most seizures. The patients volunteered for the commissurotomy, the rationale being that after the surgery the two hemispheres of the brain would be much less likely to communicate with one another and therefore seizures would not be able to propagate from one hemisphere to the other. This would preclude grand mal seizures, which envelope both hemispheres. There might still be seizures but they would not be grand mal and not nearly as debilitating.

Sperry was not the surgeon; he was the psychologist allowed to observe the behavior of the patients after the surgery. He reported a few surprising changes and was able to infer that many linguistic processes and thinking that depends on traditional logic were controlled by the left hemisphere. When information was not available to the left hemisphere (e.g., only shown to patients via the left visual field, which feeds the right hemisphere), patients had extreme difficulty labeling things (i.e., finding the words) and difficulty with traditional logic. The right hemisphere, on the other hand, seemed to govern more spatial, simultaneous processes. This was sometimes misinterpreted such that people assigned creativity to the right hemisphere, as if it was always intuitive and processed information only simultaneously and all-at-once.

Sometime later Hoppe and Kyle (1990) worked with the same patients but focused on affect and creativity. Interviews and simple tasks indicated that the "split brain patients" had difficulty with fantasy and had difficulty finding words to express feelings. The latter was taken to be indicative of "a high degree of alexithymia," which is the label given to low levels of emotionality and affect. More details about the patients were given: "their dreams lacked condensation, displacement, and symbolization; their fantasies were unimaginative, utilitarian, and tied to reality; and their symbolizations were concrete, discursive, and rigid" (p. 151). One method employed by Hoppe and Kyle involved a film, without words but with a strong emotional message conveyed through visual symbols (e.g., an empty child's swing, moving to suggest that a child had been there but was gone) and music. The commissurotomy patients viewed the film four times, and after each a method was employed to explore their feelings and reactions. In addition, while watching the film EEGs monitored brain activity. Again quoting Hoppe and Kyle:

Commissurotomy patients symbolized in a discursive, logically articulate structure, using mainly a secondary process, as opposed to a presentational structure as an expression of a predominantly primary process. They also showed a concreteness of symbolization, emphasized low rather than creative capacity, lacked a summary of the whole gestalt, showed a relatively impoverished fantasy life, and tended not to be able to convey symbolic meanings. In other words, the quality of their symbolization emphasized stereotyped denotation as opposed to being flexible and rich in symbols, images, ideas, and connotations (pp. 151-152).

Note the references to primary and secondary process, which is what eventually led to the conclusion about creative individuals differing from the commissurotomy patients in that their hemispheres cooperated with one another, sometimes in a creative way and reflecting the magic synthesis, just as [Arieti \(1976\)](#) had proposed.

Hoppe and Kyle did additional research with various control groups and offered the following overarching conclusion: “The results indicate that creative and healthy subjects tend to have freer access to mutual interaction of both hemispheres without marked inhibitory or disinhibitory effects from either cerebral hemisphere” (p. 150).

Importantly, Hoppe and Kyle also proposed that there are individuals who have not had surgery to separate the hemispheres of the brain but who behave as if they have a functional commissurotomy. This meant that they do not utilize “tertiary processes” where primary and secondary processes work together, and in fact their thinking is much like the patients in Sperry’s research. These individuals are not very creative.

Hoppe and Kyle referred to a *transformational interocclusal process*, which is another way of describing communication of the two hemispheres, but it also points to the benefit of this process, namely a kind of transformation. That transformation is what leads to creative insight. They noted that this view of creativity is consistent with Arthur Koestler’s theory of *bisociation*, a process that ostensibly allows an individual to synthesize diverse kinds of information. Hoppe and Kyle extended this idea and referred to *hemispheric bisociation*. Quoting them one last time, they proposed that “the left hemisphere follows the fixed set of rules, [and] this code governs the matrix of an overwhelming possibility of choices expressed by the right hemisphere. The “magic synthesis” of the two cerebral planes is a creative process of hemispheric bisociation (p. 153).”

Conceptual Agreement About Creativity

The methodology and results of Hoppe and Kyle are quite interesting and directly relevant to [Arieti’s \(1976\)](#) ideas about the magic synthesis. They do not offer absolute confirmation about a tertiary process, but then again in one sense it would not be reasonable to look for such evidence. That is because the theory involves primary and secondary processes. As a matter of fact much the same can be said about several aspects of the creativity complex. Creativity is not entirely amenable to absolute rigor and control. This is one criticism of the product approach to creativity: it is highly objective but not really focused on a creative process, where creation actually occurs. Research on creative products focuses on things and information about the creative process that was used to construct the product must be inferred. But the creative process described in research like that of Arieti, or Koestler, or Hoppe and Kyle, is not manifest, so it too much be inferred.

Thus it is most reasonable to consider various methodologies and levels of analysis when studying creativity, especially because it is partly affective and may often involve subjective processes, including the unconscious. Studies of creativity must use optimal objectivity rather than the methods of the hard sciences. Recall here that [Hoppe and Kyle \(1990\)](#) used a variety of methods, including interviews, manipulations (i.e., the poignant films), and EEGs.

Although there is limited empirical support for the magic synthesis, there is quite a bit of conceptual support, especially concerning the synthesis aspect of the theory and not the role of primary process. Certainly there is evidence from various sources about the role of primary process in creativity, including [Martindale’s \(1990\)](#) investigations, several of which involved the *Regressive Imagery Dictionary*. In one compelling overview Martindale described “the clockwork muse,” where creative expression varies in a predictable fashion through history as society becomes more or less inhibited and behavior more or less a reflection of primary process. There is even more conceptual support for the creative process utilizing a synthesis. [Koestler’s \(1964\)](#) theory of bisociation, mentioned briefly above, is quite consistent with a magic synthesis, as are parts of [Kris \(1952\)](#) theory of regression in the service of the ego. Then there is the work of [Rothenberg \(1990\)](#) which included experimental demonstrations of how creative insights often utilize the integration of opposites (See Janusian, Homospatial and Sep-Com Articulation Processes).

The consensus among neuroscientists is that creative ideation is *combinatorial*. This is not always tertiary as Arieti described it, but it is close. In fact current neuroscientific research also acknowledges that creativity requires networks and systems and is not localized. This too is compatible with Arieti’s views. Most important is that there are quite a few reports of how syntheses, as well as combinations and integrations, can lead to creative ideation. Standing back, all of these point in the same direction, and the magic synthesis is close to the center of that general perspective.

Combinatorial and synthetic process views of creativity both differ from constructive views of creativity which describe the origin of ideas as constructions which do not depend on combinations or syntheses. Certainly both constructive and synthetic views may both hold up; there may very well be different pathways to creativity. [Piaget’s \(1976\)](#) theory of cognition exemplifies a constructive view, especially in his idea that “to understand is to invent.” The theory of personal creativity which is summarized elsewhere in this Encyclopedia also points to a constructive rather than synthetic explanation for creativity. It describes the construction of original and effective meaning as a creative act.

Conclusions

This throws a wide net, covering the Freudian view, shared with [Arieti \(1976\)](#) in his original conception of the magic synthesis, but also citing other applications and variations of primary process as an influence on creativity (e.g., [Martindale, 1992](#)). Neuroscientific work is cited as well, including that of [Hoppe and Kyle \(1990\)](#) and the EEGs of commissurotomy patients.

One more assumption from the magic synthesis can be considered. This is the assumption is that the creative process sometimes involves a kind of reconciliation of opposites. Recall here that primary and secondary process are very different from one another. The tertiary process is only possible if there is a tolerance and acceptance of opposites. That idea is also at the heart of Rothenberg's (1990) research, and in fact it can also be found in personality studies of creativity.

There are theories of personality that describe creative people as paradoxical. The paradoxical personality includes opposing traits which seem to be incompatible (e.g., masculine but also feminine, introverted as well as extroverted, moral but also immoral) but are somehow both apparent in the creative person. Both Donald MacKinnon and Mihaly Csikszentmihalyi reported data on such paradoxical creative personalities. This is relevant because it is consistent with the view that creativity involves flexible boundaries and regular syntheses. The paradoxical personality, like the magic synthesis, is only possible if there is tolerance and contradictions are accepted as compatible rather than mutually exclusive.

The idea of a magic synthesis goes back to at least 1976. Several of the ideas are alive and well in the current thinking about creativity. The evidence for the magic synthesis is sparse, and not all rigorous, but there is conceptual agreement when a broad net is thrown and parallels with bisociation, Janusian thinking, and other examples of synthetic thought are recognized. The broadest conclusion is that there seems to be a benefit to tolerating quite divergent perspectives on creativity.

Managing Team Interactions	77
Managing Relationship With the Broader Organization	78
Managing the Work	78
Conclusion	79
References	79

To remain competitive in the increasingly changing world, organizations are placing greater value on creativity and innovation. While there are many different aspects that influence creativity and innovation in organizations, ranging from individual factors such as creative ability and expertise to contextual factors such as organizational climate and support for creativity. One important way in which organizations can facilitate creative performance of individuals and teams is through organizational leaders and their management of creative people and teams. Leaders work to create a productive internal environments or climates conducive to creativity. Internally, leaders also manage team composition, help teams take advantage of diversity, facilitate collaboration, and manage intra-team conflict. Leaders also facilitate creativity by managing resources allocated, ensuring continued organizational support, providing new information, diminishing negative organizational influences, facilitating communication within the organization, and promoting innovation initiatives.

Creative Individuals and Teams

Creative teams are composed of creative individuals, who often show a tendency towards independence and arrogance, which may increase tension in the team and team conflict. Leaders of teams are in the critical position of managing team interactions and social processes to facilitate greater team creativity and diminish tensions or other negative experiences that may inhibit creativity. Leaders should be aware that characteristics of the individuals who comprise a team influence team social processes and creative outcomes. Team diversity in relation to job functionality, educational background, and expertise, is crucial for creativity. While team diversity may facilitate creative performance, the strong personalities of creative individuals may lead to internal team conflict, which may inhibit the team's creative performance. Leaders should be aware that characteristics of the individuals who comprise a team influence team social processes and creative outcomes. Successfully guiding team interactions, and managing conflict are important tasks the leader must perform to aid creative problem-solving.

Fostering the Climate for Creativity

While creativity and innovation are viewed as desirable, and promote organizational growth and survival, creativity is often risky for organizations. Problems that require creative solutions are often complex and ambiguous. More importantly creative solutions are inherently risky because they have never been tried before, and therefore it is difficult to anticipate all the consequences resulting from implementing the solution. While ambiguous and novel situations allow space for creativity to flourish, the inherent ambiguity implies that creative efforts and ideas may fail. Consequentially, leaders in organizations may be hesitant to endorse creative ideas or products and may not be supportive of creativity by encouraging routine or well-established solutions. It is not surprising that research has shown individuals and teams develop more creative ideas when the environment is supportive of creativity and risk-taking (Hunter et al., 2005). When individuals believe their ideas and solutions are supported by leaders, they tend to feel less apprehension about sharing risky or unique ideas, thus increasing creativity.

Support for creativity and creative ideas is viewed as one important aspect of a climate that is conducive to creativity (Hunter et al., 2007). Leaders are important in creating and fostering organizational and team climate. Leaders can foster a climate that supports creative efforts in several ways. Specifically, research suggests that leaders facilitate such climate by promoting collaboration and information sharing, fostering psychological safety, and encouraging participation of team members. Promoting effective collaboration between team members is important for creative outcomes, as complex problems often require the contributions of multiple team members. Collaboration becomes particularly important to creativity when aspects of the task are subject to change, as team members must coordinate closely to ensure changes are shared within the team. Collaboration among team members requires that team members communicate effectively and openly with one another.

Such open communication concerning task-relevant information, referred to as knowledge sharing, is likewise associated with improved creativity. Leaders foster effective and open communication through creating a climate that supports information sharing and openness. Specifically, leaders are critical in creating an environment in which employees feel psychological safety.

Psychological safety refers to the extent to which employees feel secure and are willing to be true to self, without concern for negative consequences (Edmondson, 1999). Further, employees feel accepted and respected. Under these conditions, employees are more willing to share information and ideas, even when they are risky. Psychological safety is an important predictor for both individual and team creativity, as apprehension and reluctance to share ideas during brainstorming or idea generation will occur if employees feel their ideas will result in social rebuke or ostracization from the team or the leader. When employees feel psychologically safe, they perceive that ideas can be discussed openly and honestly, including discussing criticism and ideas for improvement. Leaders can facilitate psychologically safe environments by ensuring contributions are never met with negative consequences, empowering employees to participate during all discussion, and ensuring that no single individual dominates conversation (Carmeli et al., 2010).

Indeed, promoting active participation by employees has also been linked with facilitated creativity. Participation refers to individuals putting effort and thought towards group or organizational goal attainment and task completion. Participation is particularly important for team problem-solving as complex problems tend to require the knowledge, skills, and experience of each team member to effectively develop a solution. When team members interact during discussion or idea generation, team members are exposed to feedback on their ideas and potential alternative avenues to solve the problem. In turn, team members may build-up each other's ideas or combine ideas into novel solutions that more effectively solve the problem. When all team members participate and offer their unique perspectives, there is a greater chance that new ideas will arise from discussion thus facilitating the group's creativity.

Leaders can increase participation of team members by modelling open communication themselves (Boies et al., 2015). By setting the standard and expectation of an environment where individual members feel safe sharing ideas, team members may experience fewer negative emotions such as apprehension or anxiety that prevent engagement with the rest of the group. Leaders can use other strategies to encourage participation, such as preventing one single member from dominating the discussion. Alternatively, leaders can provide social rewards such as recognition or praise when more introverted team members engage with the team.

Managing Team Interactions

In recent years, more focus has been given to teams as the unit in which creative problem solving occurs. Teams are expected to be well-suited to creative problem-solving, as multiple individuals working together provides a greater pool of knowledge, wide-ranging skills, and various past experiences in problem-solving. However, with such diversity comes differing preferences, incongruent work styles, and other differences that may inhibit team performance and lead to conflict. Therefore, it is important for leaders to carefully consider the composition or make-up of their teams (Coursey et al., 2018). Discussions of team diversity typically differentiate between demographic diversity and functional diversity. Demographic diversity includes differences between team members such as gender, age, ethnic background, or race. Functional diversity refers to performance-related individual differences including job-relevant skills, knowledge, educational background, and unit of the organization.

A meta-analysis (Hulsheger et al., 2009) found no relationship between demographic diversity and creativity, while functional diversity in teams was associated with greater creative performance. Teams comprised of individuals who are different based on task relevant skills and knowledge are able to solve problems more creatively. This occurs because functionally diverse teams possess a larger pool of knowledge to draw from when anticipating and overcoming obstacles to success, and greater repertoire of past problem-solving experiences that may be relevant. However, evidence suggests that teams that are diverse, whether due to demographic diversity or functional diversity have difficulties in communicating effectively. Further, the dissimilarity between individuals may lead to misunderstandings and conflict, which are all detrimental to team performance in general and to team creativity. Managing team interactions to facilitate positive interactions and limit negative ones such as conflict are a critical aspect of managing creative people in creative teams. Leaders can facilitate positive interactions and effective communication by setting expectations, modeling appropriate behavior, and ensuring that negative behaviors be team members are not tolerated.

Team diversity is also important for team composition. Leaders can have a significant impact on the make-up of the team. When making decisions about team composition, leaders should select employees with relevant, yet varied, knowledge and skills to experience the benefits of functional diversity (Zhang, 2016). However, leaders must also work to ensure that each members' unique knowledge and skills are applied during teamwork. Fostering psychologically safe environments becomes important for functionally diverse teams to ensure team members feel secure in sharing their unique perspectives (Edmondson, 1999). Leaders can apply specific strategies in functionally diverse groups to develop their skill of being receptive to radical or novel ideas. One way in which leaders can facilitate more effective communication and reduce conflict is through facilitating shared understanding.

However, the relationship between conflict and creativity and team conflict is a complex one. Conflict can be expressed in two different ways (Jehn, 1995). Task-conflict refers to disagreements or tensions within the team concerning work-related approaches, strategies, or decisions. Relationship conflict refers to disagreements or tension within the team based on dislike and targeting a specific individual. Research suggests that relationship based conflict has a negative effect on team functioning and team creativity. Relationship conflict is particularly detrimental to feelings of psychological safety and to open communication, and therefore results in lower creativity.

The relationship between task conflict and creativity is less clear. In some cases, task conflict has been associated with greater team creativity presumably because teams that successfully navigate task conflict are able to discuss different ideas and perspectives, develop more nuanced understanding of the problem, and therefore increase creative performance. Other research suggests that task conflict may lead to less creativity, especially if there is a significant amount of task conflict. This may lead to the development of relationship-based conflict or create barriers such that teams are not able to navigate the conflict successfully. In fact, [De Drue \(2006\)](#) suggested that task conflict has an inverted-U relationship with creativity, such that too much or too little task conflict can be detrimental to creativity, while moderate levels of task conflict are most likely to be related to improved creativity.

Leaders of creative teams need to be aware of both the detrimental and facilitative effects of team conflict. Leaders therefore should create an environment in which moderate levels of task conflict can be possible, but too much task conflict or relationship conflict are discouraged. Not surprisingly, creating an environment of psychological safety can facilitate effective task conflict. When team members are able to communicate openly and honestly about disagreements regarding the task, but do so in a constructive and focused manner, task conflict can occur, but relationship conflict is limited. Leaders can further model how constructive and effective feedback, including negative feedback is provided and received, and should not allow for personal criticism and disrespectful discourse.

Managing Relationship With the Broader Organization

Leaders do not operate in a vacuum. As a result, leaders must take into account the goals of their immediate workgroup and the broader organizational goals. Leaders must also attend to restrictions posed by the organization, such as resources, time, as well as political issues within and outside the organization. In addition, leaders serve as the connection between their team to the larger organization and to the environment external to the organization including customers, suppliers, and competitors.

Resources are an important organizational issue that may facilitate or inhibit creativity and innovation ([Petrou et al., 2019](#)). Organizational leaders are critical in obtaining resources, and allocating these resources within the team. A number of studies have found that slack resources, or the availability of resources, were linked to creativity and innovation ([Greve, 2003](#)). The availability of resources allows for creativity due to the ability to allocate time and energy towards experimentation and innovation ([Amabile et al., 1996](#)). However, other researchers argue that limited resources can foster creativity. Organizations with limited resources tend to be newer organizations and allow for flexibility, which in turn facilitates creativity. Limited resources are also viewed as a challenge or crisis, which may require creativity ([Scott and Bruce, 1994](#)).

Similar to conflict, [Mumford and Hunter \(2005\)](#) proposed that a curvilinear relationship may exist between resources and creativity. While some amount of resources are necessary for creativity, having too many resources may facilitate less selective choosing of projects and investment in more risky and likely to fail ideas. That is, too little will lead to failure of creative projects, as the team does not have the time, funds, knowledge, or personnel to engage in the project successfully. Too many resources can lead to having too many projects, not eliminating projects that are likely to fail, and investing in projects that will result in less successful and less creative ideas. Leaders can be important in knowing what organizational resources are available, and how to then transform and use these resources for maximum capacity. Leaders therefore can manage creative people and creative ideas by managing the resources available to the team.

Leaders also serve the role of communicating the ideas developed by the team within the organization, further providing support for the team and its projects, including (but not limited to) resources ([Howell and Boies, 2004](#)). Leaders are viewed as boundary spanners, that is, those individuals that serve as the boundary between the team and the larger organizations or entities outside the organization. As such, they protect the team from potential negative interactions and consequences and focus on championing the team and its projects to the organizational decision makers. Leaders therefore are also viewed as potential champions for innovation. That is, leaders serve an important role of promoting the work of the team and its projects to those in the organization that can provide further support and resources for the team.

Leaders should also develop relationships with those outside of the organization. For example, in meeting consumer demands, it is critical to understand the targeted consumer and current market which can be accomplished by establishing working relationships with those who have the necessary information. Communication with competitors, suppliers, consumers, and collaborators allows a greater understanding of how the team and organization operate within the wider environment ([Scott and Bruce, 1994](#)). Research suggests that open communication and availability of market information are critical for effective idea generation. Thus, leaders can then provide teams with valuable information that was not easily accessible and more effectively facilitate new product idea generation.

Managing the Work

One way in which leaders can promote creativity and manage creative people and teams is through facilitation of creative problem solving. Leaders may facilitate creative efforts through the facilitation of effective implementation of creative problem solving processes in the team by facilitating idea generation. Research indicates that the use of facilitators or leaders who stressed brainstorming rules also increased idea generation. Further, leaders or facilitators who focused on specific rules for ideation and discussion of the ideas such as suspension of judgment, allowing everyone to speak or participate, and ensuring psychological safety

during brainstorming or ideation are critical for effective ideation were more successful. However, other research suggests that brainstorming techniques are not effective in eliciting creativity, and are no better than nominal groups (that is, individual output which is then pooled together).

While the generation of multiple ideas is important, and is thought to increase the creativity of the ideas, ideation is not the only cognitive process that matters for team creative problem solving. Processes that occur before idea generation such as problem identification and construction and information search and sharing, as well as those that occur after generation, such as idea evaluation and selection are all important for teams seeking creative solutions (Reiter-Palmon et al., 2008). Leaders can facilitate the discussion of different perspectives regarding the way the problem is conceptualized, ensuring that different views are presented, listened to, and integrated, which will result in better conceptualizations of the problem, and more creative solutions.

While the research on idea evaluation is limited, it suggests that leaders can facilitate idea evaluation and idea selection by supporting discussion of these ideas, ensuring that ideas are evaluated, and creating a shared understanding of the standards used for idea evaluation. Further, leaders need to be aware of the cognitive resources required for effective idea evaluation and provide teams with sufficient time to engage in this activity. Leaders can further aid in the idea evaluation and selection process by clearly identifying the standards used for idea evaluation, standards that typically emerge during problem construction (Reiter-Palmon et al., 2008). A clear understanding of the standards will facilitate idea evaluation creating a shared understanding and a shared framework as to how ideas should be evaluated, resulting in a more efficient and effective process.

Conclusion

While many organizations are increasingly relying on creative individuals and teams to remain economically relevant, creative employees may not receive the resources and support required to apply creative thought. Leaders and supervisors are then responsible for creating the proper culture and expectations that supports creativity. Specifically, leaders can foster psychologically safe environments where employees feel safe sharing ideas and providing their perspectives and opinions at work. Similarly, leaders that promote collaboration between employees and encourage knowledge sharing may increase employee creativity. During teamwork, leaders play an important role in managing team interactions to facilitate innovation. Leaders can make decisions concerning team membership and composition to ensure individuals from various work domains are represented in the team, thus taking advantage of the inherent diversity teams entail. When conflict arises, leaders can take steps to reduce negative impacts on creativity and can take action to facilitate employees' engagement with creative processes.

Leaders also serve as the link between the team and the broader organization. Creative thought is often time and resource intensive, and planning for complex situations may result in an underestimation of the resources necessary. Leaders can serve as champions for innovation to the organization by promoting innovation initiatives, ensuring teams are provided with the resources necessary to produce creative solutions, and maintaining organizational support for the team's continued tenure. Finally, leaders serve as an intermediary between the team and other external influences, increasing the amount of information or resources available both within and outside of the organization. Leader contacts outside the organization can provide the teams with greater understandings of the economic environment, such as competitors and trends.

A clear, concise definition of mathematical creativity is elusive. Categorizing the product of mathematical work, the solution to a problem, as creative is but one aspect of creative mathematics; a narrow and utilitarian view. Mathematics is more than solutions to problems: it is a way of thinking; it is both exploring patterns and relationships in the real world and investigating theoretical abstractions that are intriguing and may have unexpected practical applications. It is both an applied science that provides the tools and language that apply universally across other aspects of human thought from agriculture to physics, from music to politics, and a means of creative expression that allows us to define a set of conditions and explore the outcomes. The later, often referred to as pure (as opposed to applied) mathematics is part art, part science. Browder (1976) defined pure mathematics to be “that part of mathematical activity that is done without explicit or immediate consideration of direct application to other intellectual domains or domains of human practice” (p. 542) and shares several examples of how work in the field of pure mathematics often leads to applications in the sciences. Work in the field of pure mathematics requires creativity or to use Browder’s words, “innovative originality of a very high order” (p. 543).

The Relationship Between Creativity and Mathematics

In school mathematics we encountered many exercises designed to build a mathematical knowledge and set of skills that will equip us with the tools we need to solve problems. Often obscured in these experiences is the creative nature of mathematics as time is spent being shown how to solve exercises with known answers carefully selected for educational objectives rather than providing opportunities to engage in creative mathematical thought; to ask our own questions, and seek solutions to problems we construct. These types of experiences contribute to a common misconception that creativity and mathematics are unrelated. In the preface to his text on mathematical discovery George Polya (1962) describes the mathematical problems he shares with his students as case histories of solutions or a description of the “...sequence of essential steps by which the solution has been eventually discovered...” (p. viii). Polya’s effort was designed to help “...make room for *creative work on an appropriate level*” [emphasis in original text] (p. x) in the training of future high school mathematics teachers. While there is a body of knowledge to be learned, the essence of mathematics is applying and extending that body of knowledge by exploring new and interesting problems.

Creativity is an essential aspect of problem solving. E. Paul Torrance, often referred to as the “Father of Creativity,” defined creativity as

a process of becoming sensitive to problems, deficiencies, gaps in knowledge, missing elements, disharmonies, and so on; identifying the difficulty; searching for solutions, making guesses, or formulating hypotheses about the deficiencies: testing and retesting these hypotheses and possibly modifying and retesting them; and finally communicating the results. (1966, p. 6)

Problems in this context are not Polya’s case studies; those exercises found in school textbooks or mathematical competitions hopefully thoughtfully chosen to lead students to discover for themselves known successful solution methods and mathematical properties and relationships. Runco (2007) in his writings on personal creativity separates problem-solving from proactive creativity

...distinguishes creativity from problem solving because problem solving is always a kind of reaction. First there is a problem, then with a bit of luck and skill, there is a solution. Proactive creativity sometimes allows the individual to identify, anticipate, or define a problem, although these actions are different from solving a problem (Runco, p. 98)

In the 1938 text, *Evolution of Physics*, Einstein and Infeld write,

The formulation of a problem is often more essential than its solution, which may be merely a matter of mathematical or experimental skill. To raise new questions, new possibilities, to regard old problems from a new angle requires creative imagination. (p. 92)

Both Torrance and Runco define problems as thoughts, questions, curiosity, or challenges that are identified by the individual rather than given. To do so necessitates a sensitivity to the problem, an assessment of what is and is not known, and a search for solutions starting with an informed guess then testing and possibly modifying that guess until a possible solution is found and communicated to others. This creative process is in play in a classroom when a child is given the opportunity to explore negative numbers (consider controversial into the 1800s) or the properties of arithmetic as much as it is for the theoretical mathematician who is exploring motion and relationships in higher-dimensional space.

Indicators of Mathematical Creativity

Studies of mathematical creativity have defined it a variety of ways. Wallas (1926) discussed the characteristics of mathematical creativity viewing the concept through a Gestalt model of preparation, incubation, illumination, and verification. Others have described creativity in mathematics as an ability to discern relationships between techniques and areas of application and to make associations between possibly unrelated ideas. Mandelbrot's autobiographical article on the fractal universe is an excellent example of this ability. The Russian psychologist Krutetskii (1976) considered mathematical creativity as a multi-dimensional construct involving problem formation, invention, independence, and originality. Others have applied Torrance's framework of fluency, flexibility, and originality in assessing creativity in mathematics adding elaboration (extending or improving methods) and/or sensitivity (constructive criticism of standard methods).

Balka (1974) introduced a comprehensive set of criteria for measuring mathematical creative ability based on the works of Guilford; Harris and Simberg; Torrance; and Meeker. He addressed both convergent thinking, characterized by determining patterns and breaking from established mindsets, and divergent thought defined as formulating mathematical hypotheses, evaluating unusual mathematical ideas, sensing what is missing from a problem, and splitting general problems into specific sub-problems. Like Balka, Haylock (1997), and Krutetskii (1976) argued that overcoming mental fixations (or the Einstellung Effect) was necessary for creativity to emerge as if one is limited to working systematically, only using learned strategies, it is possible to try multiple methods to solve a problem but overlook a creative approach or worse label the problem as "unsolvable," then never explore other means.

Creativity needs time to develop and thrives on experience. Silver (1997) suggested, "Creativity is closely related to deep, flexible knowledge in content domains; is often associated with long periods of work and reflection rather than rapid, exceptional insight; and is susceptible to instructional and experiential influences" (p. 75). Impoverished mathematics experiences that focus only on the utilitarian aspects of mathematics and are without appropriate time to reflect, hinder the development of creativity. Education and experience build mathematical skill but without opportunity an individual's creative potential will remain dormant.

Carlton (1959) analyzed the educational concepts of 14 eminent mathematicians. From her analysis emerged a list of 21 characteristics one might observe in educational settings as indicators of a potentially creative mathematical thinker (Table 1)

She found no single defining characteristic but rather suggested that those who were mathematically creative would demonstrate a subset of these characteristics. As you read through this list notice the references to esthetics, imagination, curiosity and pleasure all of which overshadow references to ability. She identified two types of creative mathematical minds. The intuitive mind and the logical mind that works more from strict definitions, reasoning by analogy and working step-by-step. As support, Carlton cites Cajori's separation of creative minds into two categories, "the alert, quick minds and the slow, although frequently more profound, minds" (Carlton, p. 243). Hadamard (1945) believed that creativity in mathematics requires the intuitive mind with ample time for reflection and incubation of ideas. The message here is that, while fluency is important in mathematics, speed in computational tasks or rapid insight leading to a solution is not; creativity needs time to develop.

Aspects of Mathematical Creativity: Person, Product, Process, Press and a Fifth P – Problem

The Personal Touch

An individual's personality traits such as openness to new ideas, willingness to take risks and persist, curiosity, and wonder all play a role in the development of creative mathematical thought. In an effort to better define the affective aspects of mathematical

Table 1 Characteristics of the potentially creative thinker in mathematics (Carlton, 1959)

1	An esthetic sensibility, expressed in an appreciation of the harmony, unity and analogy present in mathematical solutions and proofs and in an appreciation of the structure of the field.
2	The making up or seeing of problems in data or in situations which arouse no particular curiosity in the other children.
3	A desire to improve a proof or the structure of a solution.
4	A seeking for consequences or connections between a problem, proposition, or concept and what would follow from it.
5	Desire for working independently of both teacher and other pupils.
6	Pleasure out of communicating concerning mathematics with others of equal ability and interest.
7	The speculating or guessing about what would happen if one or more hypotheses of a problem are changed.
8	Pleasure derived from adding to the knowledge of the class by producing another solution or another proof beyond those which the class has considered.
9	Pleasure out of working with the symbols of mathematics.
10	The producing or conjecturing concerning other meanings for symbols than those the teacher has revealed.
11	The making up of mathematical symbols of his/her own.
12	The tendency to generalize particular results either by finding a common thread of induction or by seeing similar patterns by analogy.
13	The ability to see a whole solution at one time or to visualize a proof as a whole.
14	Intuition as to how things should result.
15	A vivid imagination concerning the way things appear in space, the relation of things to each other.
16	A vivid imagination concerning the resulting paths or relationships of objects which have motion.
17	A tendency to speculate concerning unusual applications for the results obtained by the class.
18	The belief that every problem has a solution.
19	Persistence in working on particularly difficult problems or proofs.
20	Boredom with repetition or working of a large number of problems which she/he has well in hand.
21	Ability to perform many operations without thinking.

creativity Dr. Scott Chamberlin (University of Wyoming) and the author are working to develop a personality model of mathematical creativity based on the characteristics defined in **Table 2**.

Many of these aspects can be influenced by training and experience. One area that is frequently debated is the role of domain-specific knowledge. Studies of eminent creators suggests that a period of preparation was necessary before these individuals created new ideas, processes, and products though there are differing views on the nature of the relationships. Regardless of the theory applied, research suggests that a level of mathematical knowledge is required for creative mathematical work that advances the field. That said, mathematical creativity is not limited to new mathematical discoveries. The child who discovers for herself a relationship between problems posed in different contexts with the same underlying mathematical concepts is also creating new mathematical understanding. (For a more in-depth discussion see Kaufman and Beghetto (2009) *Beyond Big and Little: The Four C Model of Creativity*, <https://doi.org/10.1037/a0013688>)

The Role of Product

While a creative idea is the spark, a product is necessary for creativity to be recognized. A product can be in a variety forms but it should be a "... novel and appropriate, useful, correct or valuable response to the task at hand and...heuristic rather than algorithmic" (Amabile, 1996, p. 35). In seeking to develop mathematical creativity, novel and appropriate should be viewed in light of the individual's level of experience. A child's product that demonstrates new mathematical understanding is creative as is the discovery of a solution to one of the Clay Mathematics Institute's Millennium Prize problems. Vastly different in levels of complexity and mathematically knowledge and skill required but both useful and valuable to the tasks at hand.

Boden (2004) discussed the nature of creative products proposing three levels at which creative products emerge: (1) combining existing ideas to create a new product or process, (2) exploratory creativity involving the investigation of new ideas, and (3) transformational creativity; making the impossible possible. At this level reasonable guessing or problems generated by changing an initial constraint or problem input to see what results may lead to creative mathematical products.

An example of this kind of mathematical work can be found in the discovery of non-Euclidian geometries. Euclid built his geometric theorems on five postulates:

1. A straight line segment can be drawn joining any two points.
2. Any straight line segment can be extended indefinitely in a straight line.
3. Given any straight lines segment, a circle can be drawn having the segment as radius and one endpoint as center.
4. All right angles are congruent.
5. If two lines are drawn which intersect a third in such a way that the sum of the inner angles on one side is less than two right angles, then the two lines inevitably must intersect each other on that side if extended far enough.

Mathematicians spent centuries trying to prove the fifth postulate from the other four without success. In the early 1800s a few mathematicians proposed a geometry based on only first four postulates (Carl Gauss, János Bolyai, and Nikolai Lobachevsky)

Table 2 Proposed characteristics of a mathematical creativity personality

<i>Iconoclasm</i>	<i>The tendency to challenge commonly accepted practices in search of other ways to solve a problem</i>
Impartiality	Not bound to one solution approach; open to exploring alternate solution(s)
Intuition/Insight	The ability to sense the nature of problem and envision the outcome without a clear understanding of how to “navigate” the solution path to get there
Investment	An emotional contribution to finding a solution for one or more reasons
Inquisitiveness	A natural curiosity or wonder that seeks a deeper understanding of the mathematics, conjectures and new problems to explore.

leading to the development of a new non-Euclidean geometry. While Euclid’s geometry works well in our everyday lives, the new way of thinking geometrically that resulted from changing one assumption led to new many new discoveries in mathematics and physics as well as additional geometric ways of thinking. Creativity tests assessing flexibility and fluency often evaluate products in this way. [Balka’s \(1974\)](#) Creative Assessment of Mathematical Thinking (CAMT) asks participants to consider how geometric relationships would change if the only thing available to work with was a large ball on which to construct shapes.

The Creative Mathematical Process

In 1926, Wallas proposed a four-stage model of the creative process which parallels Polya’s four-step approach to problem solving ([Table 3](#)).

In the preparation phase the focus is on developing a clear understanding of the problem. What is the desired outcome? What conditions or constraints apply to possible solutions? What information is available? What information is needed? During the incubation phases ideas are considered, explored and often rejected during periods of both conscious and unconscious thought. Plans are developed tested and revised. In this process insight is gained and a solution is illuminated. Once a solution is found it should be verified by looking back asking, does it meet the conditions and constraints imposed? The difference between a creative and non-creative process is the individual’s or group’s ability to avoid constraints imposed by conventional thoughts and applications – time spent exploring and taking risks, rather than just relying on standard practices, rules, and procedures.

All too often the mathematical processes are viewed linearly – a series of steps to follow to a prescribed outcome. The work of both Wallas and Polya are often incorrectly viewed in this way. [Sheffield \(2003\)](#) offers a more iterative model of mathematics with each vertex of a pentagon representing a portion of that process. The vertices are labeled Relate, Investigate, Communicate, Evaluate, Create with each connected to the other four. The interactive nature of Sheffield’s model acknowledges the role of exploration, communication and problem posing plays in mathematical creativity.

The Impact of Press

Mathematical creativity needs a facilitative environment, not an authoritative one. Mathematicians, both those with a lifetime of experience and those just beginning to learn about the discipline, need an environment that provides time to wrestle with problems and persist in exploring ideas, the freedom to challenge the questions posed, and opportunities to work collaboratively to analyze, criticize, and synthesize information. The Math Circle movement in the United States is a notable example of this kind of environment for developing creative mathematicians. These informal communities of practice put students and advanced mathematicians together to explore interesting mathematical topics or problems. Mathematical judgment develops in such experiences and knowledge and intuition are invoked when solving mathematical problems. If one’s experience is limited to “textbook” approaches to solving mathematical problems or lecture based instruction where the individual is an observer rather than an active participant in problem formation/problem solving, there is little opportunity for creativity to develop.

The Role of Problem

If the creative outcome of mathematics is solutions to problems then creativity begins with an interesting question or problem. Speaking before the International Congress of Mathematicians in Paris [Hilbert \(1902/2000\)](#) remarked, “The supply of problems in mathematics is inexhaustible, and as soon as one problem is solved numerous others come forth in its place.” They “...should be difficult in order to entice us, yet not completely inaccessible, lest it mock at our efforts. It should be to us a guide post on the many paths to hidden truths, and ultimately a reminder of our pleasure in the successful solution.” Hilbert’s definition of a problem is not about those that mimic ones previously encountered which can be solved with a known algorithm but rather questions that are of sufficient interest and challenge to stimulate creative response.

So where do these problems come from? Ask a child and the most likely answer is from the teacher or the textbook – someone else’s problems to be solved. Problem formulation or problem-posing is an essential aspect of mathematical creativity. [Silver \(1997\)](#) writes:

Table 3 Comparing Wallas' four-stage creative process model to Polya's four-step approach to problem solving

	<i>Wallas</i>	<i>Polya</i>
1	Preparation	Understand the problem
2	Incubation	Devise a plan
3	Insight or illumination	Carry out the plan
4	Verification	Look back

...in genuine mathematical activity, problems may occasionally be presented for solution by an outside source, but it is more common for them to arise out of attempts to generalize a known result, or as tentative conjectures for working hypotheses, or as sub problems embedded in the search for the solution to a larger problem... It is in this interplay of formulating, attempting to solve, reformulating and eventually solving a problem that one sees the creative activity. (p. 76)

Creativity, Elegance, Imagination – the Beauty of Mathematics

Mathematics provides us with powerful tools that have supported advances in science, engineering, economics, technology and many other fields. As a tool it provides the ability to envision, model and predict outcomes or discover patterns and relationships. For most, the utilitarian aspects of mathematics defines the discipline rather than creative thought and applications that lead to an elegant problem solution or mathematical model, the excitement of the discovery of a recurring pattern in nature, the joy in the symmetry of a geometric construction – all examples of the beauty and mystery inherent in mathematics. In his discussion of mathematical creation, [Henri Poincaré \(1908/2000\)](#) writes:

In fact, what is mathematical creation? It does not consist in making new combinations with mathematical entities already known. Anyone could do that, but the combinations so made would be infinite in number and most of them absolutely without interest. To create consists precisely in not making useless combinations and in making those which are useful and which are only a small minority. Invention is discernment, choice. (2000, p 87)

Poincaré's work ethic followed a strict schedule for his mathematical work, spending 2 h in the morning and 2 h in the evening on his efforts to leaving time for "fruitful unconscious labor" (p. 93). This unconscious labor serves as a filter; "it is capable of discernment; it has tact, delicacy; it knows how to choose, to divine." (p. 91) identifying those ideas "susceptible of becoming conscious, [as] those which, directly or indirectly affect most profoundly our emotional sensibility." (p. 92). This emotional sensibility is a "feeling of mathematical beauty, of the harmony of numbers and forms, of geometric elegance. (p. 92). He goes on to write:

Now, what are the mathematic entities to which we attribute this character of beauty and elegance, and which are capable of developing in us a sort of esthetic emotion? They are those whose elements are harmoniously disposed so that the mind without effort can embrace their totality while realizing the details. This harmony is at once a satisfaction of our esthetic needs and an aid to the mind, sustaining and guiding. And at the same time, in putting under our eyes a well-ordered whole, it makes us foresee a mathematical law. Now, we have said above, the only mathematical facts worthy of fixing our attention and capable of being useful are those which can teach us a mathematical law. So that we reach the following conclusion: The useful combinations are precisely the most beautiful ... (p. 92)

In his article entitled *Mathematics: Creativity Imagination Beauty*, Whitcombe stresses the importance of creativity in school mathematics. While the origins of mathematics are rooted in early mankind's need to count, measure, quantify; human imagination quickly expanded our mathematical knowledge in abstract ways. In doing so our creativity gave us tools to begin to make sense of the universe we live in. The majority of the non-mathematicians' experiences with the discipline consists of the algorithms, rules and procedures in school. The beauty of mathematics, whose traits Whitcombe lists as: structure, form, relations, visualizations, economy, simplicity, elegance, and order, are lacking leading to the misconception that "mathematics is as dry as dust" (p. 15).

All mathematics today is the creative product of human imagination; invented as a means to communicate, to solve practical problems, to entertain, to search for understanding of how the systems in our world connect and function, and to explore ideas we find beautiful and elegant.

Glossary

Bradford's Law An area-specific formulation regarding the percentage of total coverage by various journals in a field. When periodicals are ranked in order of decreasing productivity in a field, the sum of articles not produced by the most prolific authors of that field is proportional to the logarithm of the number of their producers.

Cumulative advantage A principle referring to the accumulation of personal or institutional advantages as a result of the social mechanisms of scientists.

Lotka's Law Alfred Lotka's formulation about the distribution of productivity stating that the number of individuals making n contributions in a domain is inversely proportional to n^2 .

Matthew Effect Index (MI) An index showing the national win or loss for citations in positive or negative percentage numbers. The index was formulated as a ratio of the deviation of the observed citation impact from the expected citation impact divided by the expected citation impact calculated from the impact factors of all journals used for publication by a country. The index is a positive number when the observed number of citations exceeds the number of expected citations, indicating a gain situation, and a negative number when the observed number of citations is smaller than expected, implying a loss situation.

One-pass versus Multi-pass Processes: *One-pass process* refers to the consideration of a scientific discovery as being made by the person who performed the last or most critical step. *Multi-pass process* implies acknowledgement of the several contributions and phases of reworking, re-conceptualization or rejection involved in the ultimate discovery by analyzing the interactive networks among scientists.

Pareto's Law Vilfredo Pareto's empirical generalization stating that a minority of a population owns the majority of the resources, while the majority of the population shares the rest.

Price's Law Derek Price's empirical generalization that the square root of the number of all contributors produces half of all contributions.

Self-fulfilling prophecy The situations in which one's expectations can influence an outcome on the expected direction. If one defines a situation as real, it consequently becomes real.

Introduction

Creativity was once regarded as elusive, obscure, magical, and beyond the sciences. In the past several decades the field of creativity studies has become more and more scientific. This implies objectivity, some of which is a result of careful experimentation. Such

[☆] *Change History:* May 2019, Selcuk Acar updated the text throughout the article.

This article is an update of S. Acar, Matthew, Pygmalion, and Founder Effects, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 75–81.

experimentation is usually intended towards the isolation of causes and effects. Not surprisingly, several broad 'effects' are believed to govern creativity. Several terms have been coined to describe effects that explain various mechanisms with relevance to creativity. The effects to be discussed here focus on mainly noncognitive and external aspects of creativity. They are the Matthew, Pygmalion, and Founder Effects. They explain the social mechanisms of scientific creativity, the role of significant others, and the timing or primacy of scientific discoveries, respectively.

Matthew Effect

Creative productivity in sciences is critical for the advancement of our civilization. There has been debate about the relative importance of internal versus external influences on the development of scientific interests. Internal influences refer to the influence of scientists' work as isolated from others' influences. External influences refer to social, cultural, and contextual influences. Creativity is often studied in terms of internal influences: the majority of studies on creativity depend on cognitive and personality aspects of creativity. External influences have been less studied but did become the primary interest of the sociology of science. One result was the concept of the Matthew effect. The Matthew effect describes the reward and communication system of science based on the passage in the Gospel according to St Matthew, which states, "For unto every one that hath shall be given, and he shall have abundance: but from him that hath not shall be taken away even that which he hath."

Put in the context of scientific creativity and productivity, this statement addresses the issues related to the major criteria of success in academia such as publications, grants, and facilities. A dramatic expression of the competition in academia is the phrase 'publish or perish.' According to [Merton \(1968, 1988\)](#), who coined the term Matthew effects, this game is not played fairly, with some people winning every time disproportionately to their superior skills, ability, and work. He pointed to various social processes responsible for the biased evaluation system that leads "the accruing of greater increments of recognition for particular scientific contributions to scientists of considerable repute and the withholding of such recognition from scientists who have not yet made their mark." As a sociologist, he attempted to explain the reward and communication system in science in sociological terms: "the reward system [...] influences the 'class structure' of science by providing a stratified distribution of chances, among scientists, for enlarging their role as investigators."

According to Merton, science is public, not private, and the Matthew effect reflects the social climate that influences the degree to which scientists will be known by others. Merton's view emphasized external influences on recognition of scientific creativity rather than individuals' real potentials. By external influences, Merton referred to the community of scientists that may disrupt the rightful distribution of credits because of their systematically biased ascriptions.

A corollary to this proposition is differential access to facilities and opportunities called misallocation of resources that works in favor of more established and famous scientists. Inequality in the reward system provides further opportunities for known scientists and penalizes the unknown names in the field. The Matthew effect simply represents the equivalent claim as the proposition "the rich get richer and the poor get poorer" in economics. This situation reflects a sort of monopoly held by the famous scientists.

Some of the first evidence of the Matthew effect came from [Harriet Zuckerman's \(1967\)](#) interviews with Nobel laureates in the early 1960s. These indicated that 'ultra-elite' scientists receive disproportionately more credit for their contributions to science whereas obscure scientists get disproportionately little. The distribution of the number of publications is highly skewed: there are many PhD holders who publish one or no articles while a small number of scientists publish hundreds of papers as well as books. Although the skewed numbers can be attributed to other factors such as a scientist's differential ability, efforts, and career expectations, Zuckerman's findings raised some questions about the fairness of the mechanism.

Cumulative Advantage

The idea of cumulative advantage is relevant to Matthew Effects. Career trajectories of the scientists depend, to a great extent, on their cumulative advantage, defined as the social processes that determine the allocation of resources and opportunities such as laboratories, research grants, and talented research assistants and their accumulation among particular scientists and institutions. The advantages can be personal such as reputation and age of the scientists or contextual such as institutions and available resources.

Reputation is the most significant personal advantage. Social processes favor reputable authors over lesser-known authors even when both produced publications of equal quality. Even in collaborative works in which well-known scientists contributed very little, such scientists are credited with most of the work because of their reputations while other contributors receive little credit even if they invested more effort. This is true even when the famous scientist is listed last in cases where the order of authorship reflects the level of the contribution from highest to lowest. This situation persists because of the underlying preconception among the community of scientists that the famous one provided the idea, resources, and connections. This misperception paves the way for other critical decisions that help the known scientists.

When positions become available, they usually are awarded to the scientists with higher recognition, publication, and fame, who are thus able to do more research and further increase their reputations. The less-known scientist, on the other hand, will have a very limited opportunity to stay in the current position because of limited resources and facilities. Once scientists are Nobel laureates, they are Nobel laureates throughout their lives, and this title often increases the influence of their work beyond that work's merits. Their books will sell better because of the 'Nobel laureate' designation, and no journal will want to reject their papers (journals may even ask them to write papers). The ideas in the book will be read by many other people and more people will be convinced about those ideas and cite them in their own works.

Cumulative advantage specifically refers to the benefit of the early bloomers in sciences because of their relative advantages in trained capacities and locations enabling their access to resources. Studies of creativity and age show that researchers who publish earlier attain a greater number of publications than those who publish at older ages. Moreover, early publishers also produce higher quality contributions. This phenomenon can simply be regarded as normal because early bloomers will have more time to produce. From the perspective of cumulative advantage, however, this is related to the precocity bias that promotes early bloomers since early publications are assumed to reflect overall productivity. While there are scientists who cannot keep up their earlier performances and those who perform better in later years, they are fewer in number. The role of cumulative advantage is evident among older and younger scientists. Longitudinal studies of 2000 American scientists from several fields showed that the inequality between older and younger scientists has risen with respect to their number of publications and number of citations, which underlined a marked stratification. [Petersen et al. 2011](#) analyzed the careers of 400,000 scientists and 20,000 athletes and found that past success leads to cumulative advantage and careers are likely to get hindered by inexperience.

As for the institutionalized advantages, lesser-known scientists can break the cycle if they are at major universities where their publications can be disseminated among the elites of the field. Statistics indicate that a good proportion of the research grants are provided to particular universities. Grants often yield more original papers and attract more high-ability novice researchers. Likewise, many of the Nobel laureates work at particular universities such as Harvard, Columbia, Berkeley, and Chicago. In a recent empirical study controlling author quality, journal quality, and article-specific characteristics, researchers found that there are 19 elite universities that have a positive impact on the initial reception of an article and on peer recognition for its contributions. Specifically, scholars affiliated with two universities, Harvard University and University of Chicago, have a greater chance for peer recognition. This finding was limited to the departments of economics, and similar studies can be extended to other departments as well. For example, [Morgan et al. 2018](#) analyzed the role of faculty hiring on the dissemination of ideas in the field of computer science. They found that research studies originating from prestigious universities are more likely to spread better than research of similar quality from less prestigious universities. This effect leads universities hire from prestigious universities that provide them with an “epistemic advantage.”

The critical factor that distinguishes certain scientists from others is the limited awards, opportunities, and facilities provided to scientists. If only three Nobel Prizes can be granted in a year in a given category, this does not mean that only those three scientists may deserve them. However, the recognition of the scientists after they win the Prize differs disproportionately to the quality and significance of their works. The problem is that there are a few prestigious awards that could be granted to many successful and aspiring scientists. Another example is inequality in scientists’ access to laboratory and financial support to maintain their research. Although scientists working in less-known or liberal arts colleges might come up with very bright ideas, they cannot carry out their research because of teaching requirements or lack of facilities. The same situation rules when it comes to publishing papers. Academic journals have strict rules such as publishing only a certain number of articles in each volume – to the extent that only 10%–25% of submissions are accepted in the essential journals. The limited space in the journals tends to be allocated for the prolific minority rather than the novice or less prolific researchers. Furthermore, when two rival scientists with and without articles apply for a grant, their publications will be taken into consideration as well as other qualifications. Success, awards, and opportunity breed further success, awards, and opportunity, just as money breeds more money. Limited prizes, money, and facilities allotted to famous scientists distinguish them from the other colleagues.

The role of reputation for further recognition exhibits itself in the cases of ‘multiples’ when two or more researchers discover the same thing. Even though each scientist who developed or discovered the same thing deserves an equal amount of credit, respect, and recognition, the more famous one is associated with the discovery rather than the others. Some theories, such as the Darwinian Theory of Evolution, are named after the scientist, while many other discoverers who contributed to the development of the theory will not be even known and recalled by later generations. This cycle keeps going for the benefit of the more famous, and the disparity between famous and obscure researchers will increase independently from their capacities as scientists. However, [Donald T. Campbell and Herman Tauscher \(1966\)](#) noted the other direction for the attribution processes for ‘multiples.’ They indicated that scientists with unique or few contributions can be credited with a discovery rather than other scientists with many contributions because singularity of contribution provides unequivocal in the communication.

The Matthew effect is influential in the communication system through its manipulation of the visibility of scientific works. Like the influence of marketing strategies and advertisements for commercial products on their sales, reputations and the quality of previous work increase the possibility of recognition, appreciation, and dissemination of new work in comparison to a new scientist with no distinguished work beforehand. The names of the innovators sometimes overshadow the quality and importance of the innovations. When one thinks of professional conferences in any field, many researchers follow the presentations of the prominent figures in the field whereas novice researchers have fewer followers even when they sometimes introduce more original works.

Formalized Effects

Cumulative advantage may be related to various parallel effects. The so-called skewed distribution of productivity, for instance, was formalized by Alfred J. Lotka as ‘inverse square law’ based on his bibliographical studies in physics and chemistry. This formula states that the number of scientists with n publications is inversely proportional to n^2 . This formula yields a curve with many people with one or zero publications whereas a couple of researchers produce hundreds of publications. If there are 100 scientists with only one paper, there can be 25 people producing two, and approximately 11 with three papers. The number of scientists with a higher number of publications decreases asymptotically. The resulting graph is a left-skewed distribution. This formula implies that approximately 5% of scientists produce about half of all papers and the others share the other half. On the other hand, the

proportion of all contributors with only one publication is about 60%. Even though Lotka's law does not apply to all areas, recent studies about productivity proposed that it is useful in understanding the underlying pattern of author productivity.

Lack of universality in Lotka's law has been addressed by Bradford's law (or law of scatter) which was developed based on journals and articles grouped to identify the number of periodicals related to particular subjects. The process yielded a constant representing the subject area within the following formula, and used to determine the percentage of total coverage by various numbers of journals in a field: $R(n) = N \log n/s$ ($1 \leq n \leq N$), where $R(n)$ represents total number of journal articles, N represent total number of journals, and s is the constant for a subject area.

Derek DeSolla Price proposed another formula for the distribution of scientific productivity. According to it, half of the total number of papers published by N scientists belongs to $\sqrt{N}$ scientists. Assuming that there are 1000 articles in a field published by 100 scientists, 500 of them belong to the 10 most prolific scientists. Price suggested that two-thirds of the scientists publish only one paper and do not produce any more. There was a slight difference in the underlying assumption of his formulization: success increases the probability of further success, but failure does not increase the probability of later failure because lack of publication is a 'nonevent' and it cannot be counted as a publication (any event) is counted. Therefore, he suggested a cumulative advantage distribution, which is an increasing function, rather than negative binomial distribution, which can be an increasing or decreasing function, reflecting the failures and successes.

Another principle that is applied to scientific productivity is Pareto's law (also known as the 80/20 rule) originated in economics. Italian economist Vilfredo Pareto observed that 20% of the population owns 80% of the land in Italy. The remaining 20% of the land is shared among 80% of the population. This imbalance between the 'vital few' and 'trivial many' as described in Pareto principle seems to fit the distribution of the productivity of the scientists as well. A small percent of scientists owns the majority of publications and resources, while the majority of scientists own only a little.

These 'laws' reflect the inequality in productivity. Inequality in citations is even more drastic. Eugene Garfield counted the citations of 19 million articles. Of all articles cited, less than 1% were cited more than 100 times; another 3% were cited between 25 and 100 times; and 58% were cited only once in a 20-year period. Therefore, distribution in citations is more uneven than publications. However, research shows that the inequality in citations is not related to professional age, which was claimed to influence productivity in favor of early bloomers because of precocity bias.

Extensions: Countries and Journals

Other than personal and institutional aspects, the Matthew effect has also been detected at the macro level, leading some to ask if there are Matthew effects for countries. Ideally, scientific publication is only related to the content of the scientific works rather than their regional origins. However, this ideal situation may not be the case because of economic, cultural, and institutional reasons. Thus, a few countries can receive citations predominantly higher than the many other countries, which receive only a few. A Matthew Index (MI; Bonitz et al., 1999) was developed that yields a positive or negative number indicating the win/loss status of the country in citations. The MI index is higher based on the extent to which the observed number of citations can exceed the number of expected citations. The expected number of citations is determined based on impact factors of all journals in a country. The MI index is equal to the difference between observed and expected citations divided by expected citations. The resulting value is a percentage. In a study comprising 40 countries and 2712 journals, only ten countries (Switzerland, Denmark, the Netherlands, Sweden, United States, United Kingdom, New Zealand, Ireland, Germany, and Finland) had positive MI values (higher than expected citations). Analyses of the Matthew effect for countries allowed a new type of journals, called 'Matthew core journals,' which refer to 145 journals accounting for 50% of the citation wins and losses. Those journals were critical for gaining or losing excessive amount of citations.

In an empirical study, the role of the journals, in which the articles are published, was assessed by comparing the citations of identical papers in journals with high impact factor versus low impact factor. Analyses showed that impact factor of the journals played a significant role in getting citations: papers published in high impact journals received twice as many citations as their identical copies published in journals with lower impact factors. Matthew effects as associated with journals influence the citation and therefore visibility of the scientific works.

Evaluation

The Matthew effect was seen as pathology because it conflicts with meritocracy in science. Monopoly is as undesirable in science as it is in economics. However, Michael Strevens (2006) argued that the Matthew effect can be good for society and science. He argued that rewards are proportional to their contribution to society so that contribution to society is maximized. The contribution to society, then, is proportional to its epistemic security, that is, trustworthiness of the discovery or contribution. For example, a new medical treatment for an illness can have good epistemic security after it has been observed to cure the illness successfully. There should be no problem with receiving more rewards if the contributor has resolved an important problem of human beings. Based on this line of reasoning, allocation of credit proportional to the rewards is not at odds with scientific norms since this mechanism is helpful in maximizing science's contribution to humanity. According to this rival hypothesis, the Matthew effect does not seem to violate the fair distribution of credit in particular fields in which the consequences of the discoveries and their epistemic security can be tested. However, this may not be the case in many fields in the social sciences, and the Matthew effect can rule more strictly.

Limitations

The Matthew effect cannot be easily generalized to fields other than the hard sciences because some do not require many resources. For example, in the fields of the arts and literature, the Matthew effect is not dramatically observed in terms of access to resources, since the cost of writing a poem or making a musical composition requires only a pen or a musical instrument in comparison to hard sciences, which require a laboratory and grants. Nonetheless, previous works or publications in arts and literature can still determine the acceptance of future works.

Second, empirical results supporting the cumulative advantage hypothesis can be explained by some other perspectives as well. For example, some explained creativity with multiplicative functions that propose a log-normal distribution because the product of several factors that influence creativity produces a highly skewed distribution, which is different from simple addition of the same factors. The combination of normally distributed factors such as creativity, intelligence, and motivation, yields more complex effects than suggested by the cumulative advantage model.

Third, some models that are more personal in nature explain the continuity of creative productivity better than the cumulative advantage model. Simonton showed that latent factor of creative ability can successfully explain longitudinal stability of the individual differences in sciences. This argumentation takes us back to the beginning of the discussion where internal factors distinguished from the external factors. A seemingly consistent hypothesis relying on external influences can well be explained by a totally different model. Furthermore, [Simonton's \(1998\)](#) rival hypothesis rejects the early bloomer's advantage in producing more output. According to his findings, the age curve shifts but follows a similar pattern for late bloomers when their creative potential is assumed to be zero. It is the creative potential that makes the difference for productivity rather than the age of first publications.

Matthew effect warns that creative productivity in sciences is not a sole function of individual creative ability or skills, and it is manipulated by privileges, reputation, or past achievements of contributors. It is more related to the "establishment" in sciences. There are other mechanisms influencing creative productivity and the next section explores one such effect at the interpersonal level, namely the Pygmalion effect.

Pygmalion Effect

A person's perception is sometimes as important as what they are observing or considering. In part for this reason, a great deal of research has examined the ways various psychological constructs, such as intelligence, creativity, or personality, are understood by various lay groups. These understandings represent what are called implicit theories. Explicit theories, which refer to views held by scientists and researchers, are shared, tested, disseminated, and discussed. All of the theories mean they are explicit, and they may have impact on scientific work and theory construction. Implicit theories are also potentially important. They are stable yet not shared or tested. The implicit theories of teachers about creativity are extremely important. They no doubt shape teachers' expectations about students, and those expectations are critical for students' academic achievement and intellectual growth.

Creativity is influenced by interpersonal factors and Pygmalion effect is one such factor that points to the importance of beliefs and expectations of one for others. The Pygmalion effect occurs when expectations lead to actual changes in behavior. The label Pygmalion comes from a Greek myth that tells the story of a sculptor from the island of Cyprus who carved an ivory statue of a woman. She was so beautiful that Pygmalion fell in love with her. Pygmalion treated the statue as if it were an actual woman and wanted it to be real. He prayed to Aphrodite, the 'goddess of love,' who brought the statue to life. Social psychologist Robert Rosenthal was the first to name this effect, and thus it is also known as the Rosenthal effect ([Rosenthal & Jacobson, 1968](#)).

The role of expectations on human behaviors is discussed not only in the concept of the Pygmalion effect. There are other effects related to expectations, such as the Hawthorne and Placebo effects. However, the concept most closely related to the role of expectations on human behavior and that on which Rosenthal bases his definition is Self-fulfilling Prophecy. Understanding the Pygmalion effect is easier when self-fulfilling prophecy is well-understood.

Self-Fulfilling Prophecy

Like the Matthew effect, the concept of self-fulfilling prophecy was introduced by Robert K. Merton (1968). He defined it as the situations in which people's expectations can alter realities in the expected direction because the target person acts in accordance with the expectations. Self-fulfilling prophecy highlights the importance of definition of situations: "If men define situations as real, they are real in their consequences." This principle, however, works in many cases of subjective reality regarding human affairs, but not for natural affairs. Note that the definition of the situation does not have to be correct. Hence, a false definition of the situation may trigger a new behavior, which can make the false definition become true.

There are plenty of examples self-fulfilling prophecies. Think of the banking system. Can a bank go bankrupt because of rumors that it is going bankrupt? According to self-fulfilling prophecy, that is very possible! If a good majority of the investors are convinced that the bank is going to collapse soon and that they may not be able to withdraw their money unless they do that as soon as possible, it may become a reality. Their expectations, which were not true beforehand, led to a new behavior, which, in turn, resulted in what they expected. Some researchers explain underachievement of the black population in the United States with the concept of self-fulfilling prophecies. Prophesized underachievement becomes a reality.

There is empirical support for the concept of self-fulfilling prophecy. Ray C. Rist (1970) was interested in teacher–student relations based on the premise that students’ variations in success, rewards, and creativity should be considered in a larger scope, the social structure surrounding them. He, therefore, argued that the dynamics of the interaction are not uniform and hypothesized that initial presuppositions of teachers about their students’ abilities and their expectations are critical for academic achievement. Teachers, informed that certain students were ‘fast learners’ or ‘slow learners,’ treated those two groups of students differently and had different expectations. He observed that teachers have recognized that their expectations were biased and influenced by their social status and ethnicity.

How is it possible? One answer is that these expectations about others are communicated to those who are expected to behave in particular ways and that those who receive the message then react in accordance with this message and consequently confirm the expectations. The power of the message communicated is related to the subjective status of the message sender. If the person who claims a prophecy has high status in the eye of the message receiver, the message is perceived and followed as if true.

One could question the generalizability of Rist’s findings. De Boer et al., 2018 conducted a meta-analysis on the impact of teacher expectations on learner outcomes such as achievement. Interventions that focused on altering teacher behavior, enhancing awareness on the impact of expectations, and the beliefs related to the expectations improved student achievement.

The overlapping aspects of the Pygmalion effect and self-fulfilling prophecies are clear: the power of expectations. But how are they different? The Pygmalion effect could be defined as a self-fulfilling prophecy that occurs at an interpersonal level. “One person’s expectation for another person’s behavior can quite unwittingly become a more accurate prediction simply for its having been made.” Whereas self-fulfilling prophecies explain the influence of beliefs on the consequent behavior, the Pygmalion effect specifically focuses on how one person’s expectations about another person’s behavior can turn out to be a reality just for having been expected.

The Pygmalion effect is more intriguing when it is applied to creativity. First, there are some settings, like school or business environments, in which interpersonal relations markedly influence creativity. In those settings, power relations and the status of the others might play a significant role on the manifestation of creativity. The question above can be altered with that in mind: “What would happen if, for instance, teachers could change their expectations about the creativity of their students?” “Could this lead to a positive change for the students?”

Teachers and Students’ Creativity

Teachers’ expectations are especially important when it comes to creativity because studies show that there is already a mismatch between teachers’ perceptions of creativity and creativity as a construct and its correlates. Erik L. Westby and V. L. Dawson (1995) examined teachers’ understanding of creativity in comparison to the definition of creativity in previous studies. Teachers were also asked to identify their most and least favorite students. They found that teachers’ perceptions of creativity were different from those in the prior studies. Interestingly, students who are unappealing to teachers exhibited the characteristics of creative people. Teachers tend to see their favorite students as creative students, whereas they do not regard their least favorite students as creative. It is not hard to imagine that teachers’ expectations about those favorite but not very creative students will be high and that the expectations about those not favored but nevertheless creative will be low. In other words, the Pygmalion effect seems to influence some students but not all, especially the creative ones.

R. Pippert (1969) conducted an experimental design to test the Pygmalion effect for creativity. Torrance Tests of Creative Thinking were administered to 20 fourth-grade and 20 sixth-graders who were randomly assigned to experimental groups. The results of this test were given to teachers as pretest results so that they could ‘know’ which students were ‘highly creative.’ Teachers were encouraged to observe those highly creative students for their creative potential. Those names were brought up again over a period of several months. The pretest was administered again and results showed that students in the experimental group classified as creative improved their creativity scores more than those in the control group. In interviews with teachers, they were asked if they suspected the stated purpose of the study. The creativity scores of pupils whose teachers did not doubt the stated purpose were higher than the pupils whose teachers did.

In another study by Rosenthal et al. 1974, all children in grades one through six received a test that supposedly discovers creative potential. Also, they were asked to draw a man and to draw as many things as they could. Twenty percent of the children were randomly selected as ‘bloomers’ in terms of creative ability, and the teachers were informed that those children had unusual creative ability. The tests were administered again at the end of the academic year, and classrooms and teacher–student interactions were observed. Even though no overall difference was found for teacher expectancy effect, ‘bloomers’ in the fifth grade performed at higher levels than those not identified as unusually creative. Even though those results did not convincingly demonstrate the Pygmalion effect for creativity, another finding from this study underlined the role of teachers: the students with the highest score gains had teachers who are likeable, interested in children, enthusiastic, professional, and inclined to give encouragement.

Prophesying Creativity

Can we manipulate the creative performance of people by changing our expectations about them in other settings? An empirical study by Samuel J. Marwit and James E. Marcia (1967) provides an answer. They used responses to inkblot tests as an

indicator of intellectual ability. Since inkblot tests involve obscure stimuli, the responses to them can be viewed as a measure of divergent thinking ability, which has been regarded as a good estimate of creativity. They hypothesized that the number of responses given by a subject is influenced by the examiner's expectations. In the study one group of examiners predicted many responses while another group predicted few. The results showed that subjects of the former group provided 54% more responses than the latter group. In another study, examiner's expectations were manipulated regarding the possible responses from the inkblot tests by letting a group of them know that more animal percepts should be obtained than human percepts. The other group was told the opposite. The ratio of animal to human percepts was 33% higher in the former group than in the latter group. These two studies indicated that expectations about others can influence the creative responses as well as change the content of the responses.

Pamela Tierney and Steven M. Farmer (2004) tested the role the Pygmalion effect has on employee creativity in organizations. Supervisors who have high expectations about employee creativity were perceived by employees as supportive of creativity. The correlation between supervisor and employee expectations for employees' creative performance was moderate and significant. According to this study, expectations manifest their influence through intermediate steps like motivational effects and self-efficacy. Employees' self-efficacy on creativity mediated the Pygmalion effects (supervisors' expectations). This means employees who were seen as highly creative by their supervisors and reported about themselves that they had a strong creative capacity demonstrated more creativity in their works. This finding confirms the proposition that the expectations of others are communicated to them.

In another study in an organization setting, researchers hypothesized that leadership, individual problem-solving style, and work group relations influence innovative behavior through their influence on perceptions of the climate for innovation: the more supervisors expect innovative behaviors, the more a subordinate becomes innovative. The analyses showed that expectations of supervisors influenced individual innovative behavior even though this effect is specific to certain tasks such as technical tasks.

Studies of the role of expectations on creativity showed that assuming creative potential in everyone is conducive to creativity. Recognizing the significance of Pygmalion effects for creativity, thus, would be a significant addition to the implicit theories of teachers and supervisors.

Founder Effect

Recall that the Matthew effect emphasized the social mechanism of sciences that favor the famous scientists. Thomas Nickles (1994) defined another term, the Founder effect, also known as the Historical Priority effect, which refers to the importance of the timing or primacy of the scientific works. Recognition for creative productivity or a creative contribution sometimes comes from later works that build on early works that are not well-known. The idea is that some works of obscure scientists can make them famous just because of the triggering effect of the works. The Founder effect is best understood along with the Matthew effect and sometimes competes with it. Both involve the distribution of credit among discoverers. The Matthew effect highlights the role of reputation and other advantages on the distribution of credit while the Founder effect underscores the role of initiation or foundation of a new line of thought. The Founder effect represents cases where scientists made a name for themselves just because their work launched a new idea or series of research and triggered others scientists' works that in turn may have yielded a discovery. Hence the founder may not have him- or herself actually discover the key finding.

According to Nickles, two different models of creativity are possible: traditional/enlightenment and romantic models. He argued that all discoveries fall into one of these. The Enlightenment model relies more on empirical proofs, which are evaluated through inductive or deductive reasoning. Because of heavy emphasis on rational means, scientists are viewed as calculating engines. Romantic reaction to enlightenment view relies more on intuition. Instead of tracking the empirical evidence through rational processes, sensitivity to the lack of fit on the whole is viewed as responsible for the discovery. Oft-cited 'Aha!' moment in the creativity literature was a romantic understanding of creativity.

The two perspectives merge on their conception of science as a one-pass process. This suggests that scientific works are presented as if they become knowledge when they are finished like a snapshot of the final scene without elaborating on the processes of reworking, reconceptualization, or rejection. This is a simplification that reduces a whole process into 'scientist A made discovery Z' thinking. In actuality, scientific discovery is a multi-pass process. Several investigators usually make contributions, additions, or reinterpretations, each taking the problem into a different point. Because of the heavy cognitive overload involved with multi-pass thinking, and the emphasis on the individual in the history of science, it is easy and typical to recall the 'heroes' of science and ignore the complex networks that each added small blocks to the huge building. Jose Ortega y Gasset (1932) actually proposed that modern science owes much of the contribution to mediocre scientists who constitute the majority of the community. One last point about Founder effects: the initial step that provides the initiators with credit can be in the wrong direction with respect to scientific correctness, or it may be misunderstood by the real contributors who followed the founder. Some prominent examples for Founder effect are Max Planck and Frederick Banting.

Example Cases

Max Planck is known as the discoverer of quantum of energy because of Einstein and Ehrenfest, who started their works with (and misread) Planck's works. The discovery of quantum of energy, in fact, emerged years later, and Planck's solution to the problem was

abandoned. Max Planck initiated his work and got credit because he coined the term 'quantum,' while his solution eventually was not accepted. In this example, association of the discovery of quantum energy with Planck rather than Einstein can be explained by Planck's reputation (therefore, the Matthew effect is relevant in this situation because Einstein was not well known at that time) as well as his initiative for a new line of thought even though his naming was just accidental and [his] solution was not correct. In Planck's case, both Matthew and Founder effects operate together.

Frederick G. Banting's case (along with Charles Best) represents how an enthusiastic but unknown scientist can get credit for his initial work that gave birth to a significant discovery. Even though Banting was credited with the discovery and received the Nobel Prize, his work was not on the right track in terms of the resulting discovery. His hypothesis, based on the idea of duct ligation to isolate internal secretion in the pancreas, did not comply with the established facts in physiology. He was correct in addressing the problem (which concerned enzyme action) even though his work did not solve it. However, that deficit did not change the fact that Banting's idea was the first step that led other researchers to contribute to the solution. Banting was an unknown scientist when he came up with his idea. Therefore, his case represents the sole operation of the Founder effect without the Matthew effect.

The Founder effect is important to know because recognition for creative contributions may be delayed until they lead to other major contributions. The delay may take so long that some contributors do get credit in during their lifetime, which is called post-humous recognition. A recent example of the Founder effect in the field of creativity is the standard definition of creativity. The two-component definition of creativity involving novelty and usefulness is credited to different researchers and Runco and Jaeger traced the historical roots to Morris Stein's work in 1953. Stein gets recognition recently because he was the first to use two essential key terms for the first time as a definition of creativity.

Similar to the Matthew effect, the central idea of the Founder effect is the suggestion that there is more innovation in science to be recognized and, therefore, more credit to be shared among many more contributors. Nickles noted that the problem of cognitive overload can be handled by deemphasizing the individual scientists so that the role of social 'state variables' and 'forces' can be better understood.

Conclusion

Creativity is more than an individual effort and researchers recognized the role of social, contextual, societal, or system-wide influences on creative productivity. Some of these effects were objectively observed and reported in scholarly works. This chapter focused on three of these effects. First, the Matthew Effect underlines how the established system in sciences may reward some with early success or earned or presented advantages while penalizing others without them, leading further discrepancy among scientists with same or similar level of creative potential. Second, the Pygmalion Effect calls attention to the power of beliefs or expectations for creative productivity where individual creative productivity increases with higher expectations of others regarding one's creative potential. The Founder Effect refers to the critical role of earlier creative contributions that served as foundation for later creative works even though the link between the two may not be obvious or early works were not necessarily established. These three effects point to the forces above individual that may enhance or suppress their creative productivity or the recognition for it. Therefore, it is critical to be aware of such factors because they hint at strategies to maximize creative productivity of an individual or group.

The past two decades have ushered in a new era in the computerized measurement of creativity. This entry focuses on how computers are being used to measure and assess creativity both in laboratories and in the field. The emphasis is on both the computer environment—the ways are computers, or more broadly electronic devices used to measure creativity—and on the technical challenges of computerized scoring. The latter topic has seen the most growth in the area of computerized scoring of responses to verbal divergent thinking tasks. Other innovations in technology are enabling the collection and analysis of non-verbal creativity tasks, though this effort is still in the early stages of development.

The entry is organized as follows: first, the application of computerized scoring to divergent thinking tasks will be discussed. Following that, several novel paradigms for collecting creativity data in a variety of virtual environments will be discussed. Where appropriate, suggestions will be made as to how scoring should be carried out, but the purpose of this entry is not to declare winners and losers. Rather, the emphasis is on providing the reader with several leads for exploring how computers are best used in various laboratory and applied research settings.

Automated Scoring of Divergent Thinking Responses

A recent review of creativity measurement (Snyder et al., 2019) revealed that over 50% of creativity studies use some sort of divergent thinking (DT) test. The popularity of these tests likely stems from their ease of administration, but also because ideation is the aspect of creativity that can be measured across the spectrum of creative abilities (Runco et al., 2001). However, scoring DT tests is sometimes quite laborious. Several scoring metrics have been proposed including fluency—the quantity of non-redundant responses, flexibility—the number of different categories or category shifts in response arrays, originality as statistical rarity—points are awarded to responses that are not common within the sample, and originality as subjectively scored by raters. It is relatively simple to use computers to tabulate fluency scores, but the other metrics are not as straightforward. For example, Reiter-Palmon et al. (2019) noted that there is a hidden source of “researcher degrees of freedom” in many DT studies involving the organization of responses into discrete categories. For ease of further scoring, researchers might group the following alternative uses for a brick into the same category: “prop a door open,” “lift for exercise,” “hold papers in place” → *use as a weight*. This is usually a manual and tedious process that necessitates the use of multiple scorers for ensuring reliability.

The grouping of similar responses affords the variations on uniqueness scoring that quantify originality or creativity in terms of the statistical rarity of a person’s responses compared to the sample. This can be done by hand or using simple computer algorithms by simply constructing a look-up table with response categories aligned with either the percentage of the sample that listed responses in the categories, or with the points to be awarded to rare responses, as is done in uniqueness scoring. Since flexibility scoring relies on counting either the quantity of categories or category switches in a response array, categorization of responses is essential. However, the construction of computer algorithms for categorizing responses is not a trivial matter.

The difficulty in automating a categorization or *clustering* algorithm is that the responses generated during DT do not fall into neatly organized taxonomic categories. Despite this difficulty, Olteteanu et al. (2019) illustrated that it can be done by using a variety of natural language processing techniques. They applied the custom algorithm to normative data from participants who generated creative uses for 420 commonly used objects and found that it performed reasonably well. The resulting database is still rudimentary, as an analysis using the clusters on existing datasets revealed that nearly 50% of responses did not fall within the currently identified clusters. However, it is likely that larger normative efforts will enable the construction of a more inclusive set of clusters that will enable automated flexibility scoring of the alternative uses task.

Semantic Scoring

Notwithstanding Olteteanu et al. (2019) effort, the vast majority of attention in automated scoring of divergent thinking tasks is in automating the scoring of creativity itself outside of uniqueness and flexibility. In this entry, the term *semantic scoring* will be used to describe this process. The term illustrates the metrics' theoretical foundations in information retrieval and semantic memory research. That is, semantic scoring algorithms are rooted in the cognitive science of *word meaning* and as such, their validity is partly a function of the validity of the theoretical underpinnings of the approach. The objective of this scoring approach has generally been to capture the divergence (e.g., Acar and Runco, 2014) of DT responses or the remoteness of the associations that comprise the responses (e.g., Hass, 2017a). This can be done in a variety of ways, as the next few sections will illustrate. First, however, it is important to provide an overview of the theoretical and computational underpinnings of *semantic representations*—computational cognitive models of semantics.

An Overview of Computational Semantics

There is no current consensus among cognitive scientists as to the best method to computationally represent word meaning, and often the applications of a particular method dictate the representational method (Mitchell and Lapata, 2010). In addition, the quality of the representation is very much a function of source of the information used to construct it—the *corpus*. Corpora are collections of documents composed of words from some language, and a non-trivial task is converting the corpus into the semantic representation. For creativity researchers, misspecification of a corpus can lead to missing data such that a word used by a participant in a response may or may have actually occurred in the corpus (e.g., iPad will not appear in any corpus based on older textbooks).

Just as important as the form of the underlying representation of words is the means of representing *relations between words*. For example, two popular systems of representation are *vector-based representations*—word meaning is represented as coordinates in a high-dimensional semantic space, and *network representations*—word meaning is represented within a network composed of nodes, with the pattern of activity of the nodes corresponding to word meaning (Griffiths et al., 2007). In vector-based representations, remoteness of associations can be computed in terms of word similarity, which itself can be computed in terms of the cosine between word vectors. In network representations, words can be compared in terms of their patterns of activation, or in terms of the shortest length of the path between them and some other part of the network. The overarching theme here is that simply comparing the meaning of words using computational semantics is a non-trivial task.

An extra complication when using semantic scoring with DT responses, is that those responses are hardly ever single words. Instead, common responses to alternative uses prompts (e.g., brick) might contain a verb, noun, and an adverb (e.g., “use to gently prop a door open”). Vector-based representations can handle such phrases by simply computing the vector-average (centroid) over the words in the response, but that result can lead to a sort of blend of the word meanings that may not yield good specificity of the phrase meaning (Mitchell and Lapata, 2010). Network representations can, in theory, handle phrase-level data, however, fewer researchers have attempted it (but see Georgiev and Georgiev, 2018). As such, the majority of applications of semantic analysis to DT responses are rooted in vector-based semantics, and that will be the focus of discussion.

Applying Semantic Representations to DT Responses

Forster and Dunbar (2009) illustrated a key aspect of the use of vector-based semantics for scoring alternative uses responses: the basis of comparison matters. In their study, they used latent semantic analysis (LSA), a vector-based representation of word meaning constructed using matrix transformations to reduce the dimensionality of a term-document matrix—a representation of word co-occurrence in a corpus that ignores word order (for more detail see Landauer and Dumais, 1997). The result of the dimensionality reduction is a set of factors, not unlike those distilled from factor analysis, and the “scores” of words on each factor comprise the coordinates of the word-vector. Vectors are then compared using the cosine similarity metric, which provides a relatively good analogue to human similarity judgements (Landauer and Dumais, 1997).

Forster and Dunbar (2009) compiled several different metrics, each employing the cosine similarity between various responses. The two most relevant measures were two variants on originality: “relative” (quotes added) originality—originality defined by comparing each response to a vector average of 25 randomly selected responses, and “common-use” originality—originality defined by comparing each response to the most common use for the object given by a separate set of participants. Both measures had a positive association with fluency: the more fluent a participant was, the more similar, on average, his or her responses were to either the common use of the object or to other participants' creative uses. In addition, elaboration—the sheer number of words in each response—was negatively correlated with similarity. However, only the common-use measure correlated highly with human judges' ratings of the responses. This suggests, that at least part of what human judges assess when rating the originality or creativity of alternative uses responses is the similarity (or lack thereof) between a given creative use and the common use for that object.

In two analyses Hass (2017a,b) investigated a similar scoring procedure. Rather than solicit normal uses for objects, Hass used LSA to compare DT responses to composite dictionary definitions of the prompt objects as a means to standardize the technique. Hass (2017a) illustrated that there was a reasonable correlation between semantic distance and human judged originality of responses using a previously validated dataset. In addition, he showed that participants with higher fluid intelligence scores produced more semantically distant first responses indicating that the semantic scoring technique captured previously identified

relations between DT, remote associations, and fluid intelligence. Hass (2017b) further showed that the semantic similarity of DT responses decreased across the first few responses, which is consistent with the serial order effect in DT (Hass and Beaty, 2018). These results lend further support for the use of LSA-related semantic scoring for capturing critical aspects of the DT idea generation process.

Despite these positive results using LSA methods for semantic scoring, there are some issues with the methodology and several alternatives. First, the number of words in a response can bias the LSA derived scores leading to issues in interpreting results across studies (Forthmann et al., 2018). This is particularly important if LSA is used for scoring other verbal DT tasks such as the consequences task that generally lead to wordier responses. Harbison and Haarmann (2014) provided scenarios to participants such as “a light in the darkness” and asked for creative responses to the scenarios. They then compared the performance of LSA-based scores with scores based on Pointwise mutual information (PMI). PMI is an information-theoretic metric that is based on an “n-gram” analysis of a corpus. An n-gram analysis entails tabulating sets of n words in a corpus in order to derive the transition probabilities between words.

Harbison and Haarmann showed that PMI-based analysis outperformed LSA when used to examine the first content word in responses. However, PMI cannot handle phrase-level data in the same way that LSA can, and relies on a much larger corpus than LSA does, so it is unclear how effective PMI can be in scaled up applications. Finally, a related algorithm for processing corpora, latent Dirichlet allocation (LDA), shows some promise for augmenting semantic scoring techniques as evidenced by its use in analyzing real-world idea generation (Chan and Schunn, 2015). Deriving valid DT metrics using LDA is more complex than using vector-based comparisons because the result of LDA is not spatial representation but rather a set of “topics” comprising different words in the corpus (see Griffiths et al., 2007). These topics represent a kind of feature-based representation similar to classical theories of object recognition, and preliminary analyses show that the method can at least represent the features of various DT object domains (Hass, 2018). However, there is still more to do to demonstrate that these so-called “topic models” can be validly applied to DT scoring.

Beyond vector-based representations, Acar and Runco (2014) found success quantifying the remoteness of associations contained in DT responses using information from different databases that represent word associations: WordNet, the Word Association Network, and IdeaFisher. WordNet (Princeton University, 2010) is a database that represents word meaning using conceptual and lexical relations between words rather than computing relations via co-occurrence data, as is done with LSA. The database lists “synsets” for words, which are like synonyms are more complex, and include other lexical information beyond synonymy. Similarly, the Word Association Network (<https://wordassociations.net/en/>) uses a set of algorithms to produce sets of associates for thousands of English words, as does the IdeaFisher tool, though the information about how these tools compile the lists is proprietary. In all cases, the tools generate a list of associates for English words, but the underlying representation is not vector-based.

Acar and Runco (2014) used the three databases to construct a categorical scoring scheme for DT responses: “close associates” were responses with all words appearing in the databases, while “remote associates” were responses with no words appearing in the output from the databases. Since WordNet lists were generally much longer than the other two databases, Acar and Runco added a “moderate” category and responses in that category were those in which at least one word appeared in the WordNet lists. The scores derived from each database showed good internal consistency, and were moderately correlated with self-reported creative “attitudes and values.” In a follow-up study, Beketayev and Runco (2016) again showed that association-based scoring was reliable, and that a new metric: item originality—an average of the association statistics across 12 association networks—was also reliable.

Though the details of the methods are unclear, Beketayev and Runco provided evidence that algorithmic originality scores are possible to compute without the use of LSA. Indeed, in a recent study, Georgiev and Georgiev (2018) successfully used a WordNet-based method to quantify divergence and convergence in real-world creative problem-solving conversations. Georgiev and Georgiev (2018) formalized several graph-theoretic and information-theoretic metrics for further use, and there is clear potential to adapt these methods to score specific tasks used by psychologists.

Summary

Despite some lack of clarity on what the gold standard should be for assessing the use of semantic scoring methods, there are clear advantages from such approaches. LSA-derived scores seem to capture some critical aspects of the idea generation process, and illustrate construct validity and reliability. Network analysis also holds promise for scoring DT responses, but given that such an approach has only begun to penetrate psychological research, it will likely take more time to validate such methods. Early efforts at automating the categorization and clustering process implicit in many DT studies are also showing promise, and present a practical way for standardizing the cleaning process used by most DT researchers. However, the most important three aspects to consider when using these methods are the corpus used to train the representation, the form of the representation itself, and the mathematical and conceptual formalisms at the heart of the algorithm’s details. Without consideration of these details, semantic scoring techniques may lack some of the validity shown in the reviewed analyses.

Use of Computers Beyond Divergent Thinking

Though DT is often the target of computer-based assessment and scoring, researchers have begun to apply computerized techniques to creativity tasks beyond verbal divergent thinking. These applications generally represent the use of computers for collecting data

in novel experimental paradigms or over the internet. Both of these approaches are extremely important for the broader application of creativity measurement and assessment in industrial and educational settings and for the continued push for more domain-specific, and ecologically valid creativity tasks for use in laboratory research. It should be noted that several analyses have shown that DT tests can be reliably measured via the Internet, with the same validity as face-to-face DT testing (e.g., [Acar and Runco, 2014](#); [Hass, 2015](#)). Rather than discuss those efforts, the remaining sections of the paper will focus on computerized and Internet facilitated brainstorming, as well as domain-specific applications of computers to creativity research.

Group Brainstorming

[DeRosa and colleagues \(2007\)](#) conducted a meta-analysis of electronic group brainstorming research that compared the use of computers in the process to face-to-face group brainstorming as well as control conditions in which electronic group efforts were compared to “nominal” electronic groups – averages across individual brainstormers working at computer terminals. They concluded that though electronic groups brainstorming together via computer applications outperformed face-to-face groups on the quantity and quality of ideas produced, there was little difference between groups using electronic collaboration software, and the nominal groups, who did not interact via software. However, further analyses revealed that group size moderated the effects such that electronic group brainstorming was superior when group sizes were large. The major takeaways from the analysis were that use of collaborative software in medium to large size groups improves the quantity and quality of ideas most likely because such software acts as an external memory device (all generated ideas are displayed to users through the session) and can reduce pressures of social etiquette that might prevent the voicing of ideas in face-to-face sessions.

The merit of electronic brainstorming work is that they seem to afford the study of idea-generation problems with more complexity and domain-specificity than classical DT tasks. However, it should be noted that in all of the studies reviewed, scoring was carried out by hand, with limited effort to apply semantic algorithms, even though verbal responses were almost always collected. Indeed, in most cases, brainstorming research uses the same quantity and quality metrics outlined by DT researchers (fluency, uniqueness, and subjective creativity ratings). Given the different origins of DT and brainstorming, it is not surprising that there is limited cross-talk between the two research fields. With the advancements in algorithmic scoring of DT responses, there is fertile ground for growth of algorithms to sift and score responses collected via electronic brainstorming software.

Domain Specific Applications

One of the most promising areas for further work in computerized creativity measurement and assessment is in the development of non-verbal tasks and domain-specific tasks that go beyond brainstorming and DT. As with verbal divergent thinking data, there is a need for automated scoring of verbal responses in all areas of verbal creativity. [Wang et al. \(2008\)](#) illustrated that vector-based representation of responses to a problem in earth science (debris flow) could be used to quantify both problem finding—a surrogate of exploration or divergence—and problem solving; ostensibly convergence. Participants in Wang and colleagues’ study were given a scenario describing the debris-flow hazard represented by an ensuing mudslide. They were then asked to two questions: “what are the possible factors underlying debris flow hazards” and “what are the possible solutions for preventing debris-flow hazards.” Students were encouraged to generate as many responses as possible for each question. Responses were converted to a vector-space model similar to that used for LSA. Rather than use an underlying corpus, Wang and colleagues used the vector space model to categorize responses based on human coding using a heuristic method and two machine learning algorithms: a support-vector machine classifier and a regression approach. The aim of each method was to output a grade for each participant that quantified divergence and convergence. All three methods were able to provide output that fit well with human-graded responses, though the algorithms used were more complex than those used for LSA-based semantic scoring. As with the LSA-based approaches to DT scoring, Wang and colleagues emphasized the quality of the training data and human coders’ work as critical to the success of these algorithms. However, the effort to tailor algorithms to a specific domain in education illustrates the potential for more work in this direction.

In the debris-flow study, Wang and colleagues identified problem-finding as an important aspect of the creative process. Problem-finding—also known as problem identification or problem construction (e.g., [Reiter-Palmon](#) this volume)—is not explicitly measured in DT tasks. Tasks that require participants to indicate their thoughts about the problem domain itself, such as in the first question in the debris-flow study illustrate that search of knowledge may be an important determinant of creative problem solving (see also, [Hass, 2017b](#)). In a novel approach to information search, [Kerne et al. \(2008\)](#) combined “information discovery” with creative ideation using computers. Psychology students were asked problem-finding questions (e.g., “what psychological factors can influence a person’s career choices”) and presented with a computer interface that allowed them to search for information related to the question and compile a hybrid text-and-image based “answer” with specialized software (combinFormation). Students’ answers were then scored with a rubric for “emergence ... qualities [that] come newly into existence as a result of novel combinations of elements” (p. 468). Though the task of electronically assessing emergence was not undertaken by Kerne et al., their use of a search mechanism and specialized software for answer composition represents an exciting avenue for future work across domains.

Nearly all of the methods reviewed involve verbal solutions to verbal problems. However, a few researchers have made significant headway on this front. For example, [Barbot \(2018\)](#) illustrated the feasibility of measuring fluency and response time data

using computerized versions of figural items similar to items on the figural form of the Torrance Tests of Creative Thinking. Participants drew their responses into a custom interface which then tracked response time as a means to segment the drawing process into exploration, production, and verification phases. Though Barbot's report was a feasibility study, the effort illustrates the potential of this assessment paradigm, especially in studying children and other populations for which verbal ability may be underdeveloped.

Muldner and Burleson (2015) engineered a computer drawing environment in which participants worked through geometric proofs with both text and figures. Muldner and Burleson also used eye-tracking, EEG, and skin conductance sensors while participants constructed their proofs. Though the creativity of the proving process was quantified with traditional measures (fluency, flexibility, and uniqueness) the combination of creativity and sensor data allowed for examination of correlations between creativity scores and the data collected via the sensors. There were significant differences in saccade patterns between participants with high creativity scores and those with lower scores on the proving tasks. Though the sample size was small, the study, like Barbot's method, demonstrated how traditional creativity scores can be integrated with domain-specific, non-verbal problems represented with computer technology.

Conclusions and Future Directions

Much has transpired in the last decade to move creativity measurement and assessment into the digital age. Though emphasis was initially on computerizing and automating verbal divergent thinking tests, transdisciplinary efforts, especially in STEM and design fields, are yielding a variety of applications of computerized methods to domain-specific tasks, electronic brainstorming, and creativity support systems. Though the latter was not the focus of the entry, it remains an important part of the effort toward understanding how computers should be applied to creativity research questions.

Not surprisingly, there are still difficulties in fully automating the evaluation aspect of many creative tasks. Semantic scoring of verbal creative ideation has seen the most development, but there is still much work to be done to scale up semantic scoring efforts. In addition, many domain-specific applications feature the novel use of computers as data-collection systems, but still rely on human-mediated evaluation procedures. It may not be possible to fully remove the use of judges or coders from all scoring processes, and indeed, human coding plays an important role in the design of any machine-learning or prediction algorithm (Wang et al., 2008). That said, using computerized means to collect creativity data at the very least reduces the load on researchers by providing structured data to analyze. Notwithstanding the limitations still inherent in computerized data collection and analysis in creativity research, the future is certainly very bright.

Introduction

Creativity, it is commonly argued, can be analyzed by looking at creative products, creative processes, creative personalities, and creativity-enhancing environments (Rhodes, 1962). All are important, but only one is essential: creative products, without which the term “creativity” becomes meaningless. A creative process, creative personality, or creativity-enhancing environment that never produced anything that might be judged creative would belie the adjective “creative.” In contrast, an artifact deemed creative can be justifiably described as such even if there was no evidence of any creative processes, creative personalities, or creativity-enhancing environments involved in its production. Even nonhuman creators — including both animals and computers — can be creative in the sense that they produce things that appropriate experts might judge to be creative.

Consider what would be required to make a case that a particular thinking process, personality, or environment was in some way a creative thinking process, creative personality, or creativity-enhancing environment. One might build such theories, but to test them there would at some point need to be a connection of some product that could be judged to be creative. Unless someone actually does something that might be judged to be creative, it is hard to argue that the person, the thinking processes that person might use, or the environment in which that person is working is creative in any meaningful or defensible sense. The product might be some lasting creation or a more ephemeral product such as an idea, but unless the thinking process, personality, or environment could be connected with some creative products it would be impossible to make a claim that it was a “creative” thinking process, personality, or environment. It can be argued, therefore, that assessing creativity by judging the creativity of actual creative products is the most basic, and most essential, kind of creativity assessment.

The Consensual Assessment Technique

In 1982 Teresa Amabile published a paper describing the Consensual Assessment Technique, which is the primary method used by psychologists today to assess the creativity of products of all kinds. The key idea is simple: experts in a given domain are the people who best understand and are in the best position to assess the creativity of products in that domain. When Nobel Prizes, Fields Medals, or Academy Awards decisions are made, they are not made by either polling a random sample of people or asking creativity experts to develop creativity-assessment rubrics. Similarly, when using the Consensual Assessment Technique, experts in the domain in question are asked to judge the creativity of products in that domain. Collages, poems, and stories have been the most widely used in psychological studies (in part because almost anyone can create such artifacts, whereas most people would come up empty if asked to do things like compose a musical score, create a computer app, or develop a cosmological theory), but in principle the Consensual Assessment Technique could be used to assess the creativity of any kind of product or artifact (including both things that have taken years to create, such as a novel, and spontaneous things, like a joke; Kaufman et al., 2008; Luria et al., 2018).

Consensual Assessment Technique judgments can use a Likert-type scale or they can rank-order the items being judged. In all cases, all of the expert judges assess the creativity of the same pool of items, and the judges work independently in making their assessments. (In general, the experts do not even know who the other experts are, and in no case should they have any opportunity to confer with one another until after all assessments have been made.) When experts (typically 5–15) independently make such creativity assessments, inter-rater reliability is typically quite high, usually 0.80 or higher, as measured by coefficient alpha. And when different groups of expert judges assess the creativity of different creative products of the same kind (e.g., two or more poems, two or more stories, or two or more collages) produced by the same person, the results evidence considerable consistency, even over time.

But one might very reasonably ask, “Don’t expert judgments of what is creative change over time?” They do, of course, although probably much more so in the case of cutting-edge, paradigm-shifting, genius-level creative products than in the garden-variety creativity of subjects in most research studies. But even if they do change over time, what the Consensual Assessment Technique provides is the best possible assessment at a given point in time, an assessment that might be different in a different century but that is unlikely to be much different in a year or even a decade.

There has been some controversy regarding what constitutes expertise and even if expertise is needed when using the Consensual Assessment Technique. Experts are far fewer in number, and much more expensive to use, than novices (often undergraduates, who are both plentiful and cheaply hired), but research has shown that in most cases actual experts in the domain are indeed needed. Novice judges often do agree with one another (in the sense that, with a large enough group of novice judges, it is possible to get acceptable levels of inter-rater reliability), but although they agree with one another, the judgments of novices often are at odds with those of experts in the domain. There are times when what one might want is a poll of non-expert opinion (such as People's Choice Awards) rather than expert opinion, but not, generally, if one's goal is assessing creativity. For this reason, the validity of any non-expert judgments can only be assumed if it has been demonstrated in a given domain (and for a specific task in that domain) that the creativity ratings given by novices of a certain type (e.g., quasi-experts who have considerable familiarity in a domain but not clearly recognizable expertise) closely match those given by experts in that domain. Simple inter-rater reliability can provide evidence of validity only with the use of experts in a domain — or with judges whose creativity ratings have been demonstrated to match those of such experts (Baer et al., 2009; Kaufman et al., 2009; Kaufman et al., 2008; Kaufman et al., 2013).

The need for the domain experts to judge the same set of products puts some limits on ways the Consensual Assessment Technique can be used. It is not possible to standardize such assessments, at least not in any reasonably cost-effective way. A given groups of items being judged could, as a group, be more or less creative than a different group of items of the same type. If, for example, one group of collages had been created by a group of middle school students and another group of collages by elementary school students, the collages in the former group would tend to be more creative, on average, than those in the latter group (Baer, 1993, 1996). If a collage were included in the former (more skilled) group it would receive lower creativity ratings than if it had been included in that latter (less skilled) group because all comparisons are relative to the specific group of products being judged.

This limitation can be partially offset by using groups of similar participants. If, for example, one had 1,000 short stories written by high school students to judge for creativity, it would be difficult to have a single set of expert judges rate each of the stories in comparison to the all of the other 999 stories in the sample. (Not only would it be difficult to keep such a large set in mind, which might result in shifting standards as experts worked through the set of stories. Simply finding experts willing to take on such a task would likely be problematic!) But if one divided the 1,000 stories randomly into 20 sets of 50 stories each and then had groups of experts rate the creativity of the stories in each set in comparison to the other stories in that set, scores obtained on stories in each set might fairly safely be compared. The experts who rate each set of papers might be entirely different, or there could be overlap. What is important is that the stories be rated for creativity in comparison with the other stories *in that set* and that the full range of possible scores be used in the ratings. Judges need to be coached to give roughly the same number of ratings at each level — this is to avoid rating nearly all the papers at the same level, which would provide very little discriminatory power — and to use more than a small number of levels. If just a two-level (high or low) or three-level (high, average, or low) scale is employed, differences in creativity may be obscured. Five or more levels — or at the extreme, a rank ordering of the entire set of products — provides greater discrimination.

In judging assessment methods, psychologists look for both validity (Is the test measuring what it is supposed to be measuring?) and reliability (Are the results of the assessment consistent?). Both are necessary; having one without the other is no better than having neither. For example, a test that gives consistent results but that is measuring something other than what it says it is measuring (such as a test of knowledge of history that is really only measuring reading comprehension; a clock that is broken and always gave the same time; or a test of creativity that is actually measuring extroversion or self esteem) would be worthless. Similarly, measurements that are erratic (such as an exam that different readers give widely varying scores; a ruler made of an elastic material that expands and contracts depending on the temperature; or a creativity test that produces widely varying scores depending on which version of the same test one used) would be of little use. (In fact, both kinds of tests could be worse than having no test at all, because users of the tests would believe, based on test scores, that they know something that in fact they do not know.)

Creativity assessment has been hampered by the need for both reliability and validity. Other types of assessments based on things like personality profiles, tests of thinking skills of various kinds, and self-assessments of creativity always need to come back, in some way, to validation via actual creative performance. This is an important advantage of the Consensual Assessment Technique, which is rooted in creative performance. The validity of Consensual Assessment Technique assessments is underwritten by the knowledgeable judgments of the experts in the domain in question. (If one is going to judge the creativity of, say, a painting, one would use recognized experts in the field — such as painters, art critics, art teachers — as judges. What could possibly supersede their combined judgment of the creativity of a group of paintings?) The reliability of Consensual Assessment Technique assessments is measured by the degree to which the ratings of experts, working independently, agree with one another. No other method for assessing creativity has such built-in validity and easy-to-measure reliability.

The Consensual Assessment Technique does have one major drawback: it is very resource-intensive. Unlike a quick self-assessment or skills test, participants must first actually create something. Then experts in whatever domain the assessment is taking place must be employed to examine and judge each of the things the participants have created, one by one and in comparison with all the other creations in the group, which typically means examining each creative product multiple times. The Consensual Assessment Technique has been deemed the “gold standard” of creativity assessment because of its validity and reliability, but perhaps the term might also apply to its expense (in terms of both time needed to use the technique and money needed to compensate expert judges), which can be considerable.

Applications of the Consensual Assessment Technique

The Consensual Assessment Technique has been widely used in creativity research. Pioneered by Refs. [Amabile \(1982, 1983\)](#) for research in the social psychology of creativity (with a focus on intrinsic motivation), it has since been used in creativity research of all kinds. It has been especially useful in looking at the question of the degree to which creativity is domain specific (i.e., are creative thinking skills, creative work habits, creative personalities, etc. the same, or even similar, across domains, or do they vary by domain?). Amabile originally used the Consensual Assessment Technique as a general measure of creativity, under the assumption that the domain she happened to choose was not a significant variable. She used primarily story-writing, story-telling, poetry-writing, and collage-making as her tasks because these were tasks that almost all potential research participants could complete. The Consensual Assessment Technique does not assume either domain specificity or domain generality, however, so unlike other kinds of creativity assessments (which almost uniformly assume domain generality), the Consensual Assessment Technique provides an assumption-free method of creativity assessment that is ideal for such comparisons.

The Consensual Assessment Technique is also used for admission to special programs, such as creative writing, science, and engineering programs, and for awards programs ([Baer and McKool, 2009, 2014](#)). In many ways the Consensual Assessment Technique is simply a formalization of ways to assess creativity that have long been used in educational and award contexts. Asking experts in a domain to assess the creativity of things applicants or candidates have created long predated the 1982 birth of the Consensual Assessment Technique. The formalization of this process through Consensual Assessment Technique procedures has made it possible to measure the reliability of these procedures and to document the conditions under which they are valid.

The Creative Achievement Questionnaire

One can assess the creativity of discrete products (using the Consensual Assessment Technique or less formal procedures, such as those used in many competitions or admissions decisions that stress creativity), but one might also be interested in long-term creative productivity. One procedure that has shown evidence of validity in making such assessments is the Creative Achievement Questionnaire.

Development of the Creative Achievement Questionnaire followed five key principles:

1. Creative achievement is best assessed in a domain-specific manner. Achievement in one area of creative endeavor (painting, architecture, or scientific discovery) does not necessarily imply creative excellence in all areas. However, many individuals boast accomplishments in more than one domain of endeavor. The CAQ was therefore designed to identify specific domains of achievement as well as to provide an indicator of total accomplishment across multiple domains.
2. Creative achievement implies exposure to, and acquisition of knowledge and skill in, the appropriate domain of endeavor. The CAQ was therefore designed to provide an indicator of training in domains of creative accomplishment.
3. Recognition by experts in the domain is the most valid and practical criterion for judgment of accomplishment. The CAQ was therefore based upon public acclaim ranked by field “experts.”
4. Recognition of an achievement by a broad range of experts rather than a narrow range implies greater accomplishment. The CAQ was therefore designed to give more weight to national than to local awards and acclaim.
5. Fewer individuals attain higher levels of achievement. The CAQ was therefore designed so that the levels of achievement acknowledged by the fewest individuals received the most weight. ([Carson et al., 2005](#), p. 39, p. 39)

The Creative Achievement Questionnaire is an indirect measure of creative products in a wide variety of domains. It asks respondents about specific, notable, and public accomplishments in each of those domains. The domains assessed using the Creative Achievement Questionnaire are visual arts, music, dance, creative writing, architectural design, humor, theater and film, culinary arts, inventions, and scientific inquiry. Validation of the Creative Achievement Questionnaire has included assessments of the creativity of actual creative products using the Consensual Assessment Technique.

In some ways the Creative Achievement Questionnaire is a self-assessment, and creativity researchers have many reasons to distrust creativity self-assessments. The Creative Achievement Questionnaire avoids that weakness better than most self-report scales by asking about specific kinds of accomplishments, such as (in the visual art domain) “My work has won a prize or prizes at a juried art show” or (in the writing domain) “My work has been reviewed in national publications” ([Carson et al., 2003](#), p. 500). There is still substantial room for subjective judgments, however, which may result in considerable error. For example, one “Scientific Discovery” question asks how many research grants the participant have been awarded. Some respondents might include small internal seed grants or travel grants, whereas others might assume this refers only to major federal funding grants. The scales used in many do not specify or in any way account for significant gradations of awards, conflating local, regional, and national awards as well as awards by groups with highly different standards (including, perhaps, pay-to-play publications and conferences in which anyone can have their work accepted).

One review also noted a problem the authors termed “implausible values”:

In theory, the CAQ’s items function as stair steps: people shouldn’t endorse the high-achievement items without also endorsing the preceding items. For example, no one should endorse “I have been paid to act in theater or film” without having endorsed the earlier item “I have performed in theater or film.” But some participants have aberrant response patterns, such as endorsement of only a single high value or endorsement of illogical patterns of accomplishments. It isn’t clear what to do with such response

patterns, and the literature on the CAQ to date has not discussed it. (Only a small percentage of a sample will have unusual patterns, but this subgroup can have a large influence simply because they are part of the minority that didn't get a score of 0 or 1.) (Silvia et al., 2012, p. 21, p. 21).

Because the Creative Achievement Questionnaire focuses on significant, observable accomplishments, most people will score low, producing strongly skewed scores with most people piled up at the low end of the distribution; only people who have made significant achievements in at least one domain can possibly receive high or even modest scores on the Creative Achievement Questionnaire. The Creative Achievement Questionnaire is therefore only useful for making discriminations among people who have made significant accomplishments of some sort; in fact, most people receive scores of zero in all ten domains. There is virtually no discrimination possible among participants, such as elementary school children, who have had limited opportunity to make notable creative achievements.

The Creative Achievement Questionnaire provides creative achievement scores for each of the domains it measures. Although some factor analytic work has been done, it is not clear how or if these ten scores can or should be reduced. Silvia et al. (2012) noted that "the factor analytic evidence for the CAQ is still preliminary. Neither of Carson et al.'s factor solutions included all 10 domains, and the analyses did not seem to take steps to accommodate the serious skew in the scores. Additional research (particularly work involving confirmatory models) is needed" (p. 22). For research in which participants can be expected to have made fairly significant accomplishments in one or more domains, however, the Creative Achievement Questionnaire is both much simpler to use than the Consensual Assessment Technique and is a measure of lifetime creative achievement, not creative achievement on a single task such as writing a poem or creating a collage. For most research studies with participants who have not (yet) made significant creative achievements in any domain, however, the Consensual Assessment Technique is the better choice.

Introduction

Over the past several decades, researchers and practitioners have shown a growing interest in the assessment of creativity, developing a number of different approaches to measuring it. These approaches include attitude and interest inventories, biographical inventories, divergent thinking tests, environmental climate inventories, judgement of products, personality inventories, ratings of eminence, ratings by peers, teachers, or supervisors, and self-reports of creative activities. Many of these measurement approaches utilize self-reports (i.e., attitude and interest inventories, biographical inventories, personality inventories, self-reports of creative activities). Creativity self-report measures can assess the extent to which an individual perceives themselves to hold the personality traits or cognitive processing abilities to produce a creative product. Creativity self-report measures can also assess an individual's engagement in creative activities. Commonly used for their convenience and feasibility, creativity self-report measures have been used as a predictor of creative performance, creative achievement, creative effort, and creative potential, as well as a criterion for creativity.

Types of Self-Report Creativity Measures

Creativity is often defined as the production of an idea, artifact, or behavior that is considered both novel and appropriate. The definition of creativity involves four aspects: person (what characteristics make up a creative individual), product (what is considered creative), press (what contextual factors facilitate or inhibit creativity), and process (what is the procedure to arriving at a creative product). Indeed, creativity is a multifaceted and complex construct, which results in multiple and differing approaches to measurement, even in the context of self-reports.

Creativity researchers proposed several different taxonomies for creativity self-report measures. For example, [Batey and Hughes \(2017\)](#) classified self-reports into measures of either product, process, or trait. They proposed that products measure creative achievement, or the extent to which a person has creative accomplishments in a variety of domains. Process measures ideational behavior, or the extent to which a person believes they exhibit creative behaviors. Traits measure constructs such as creative self-efficacy (the extent to which a person believes they are creative), self-rated creativity (the extent to which a person considers themselves to be creative), creative personality (the extent to which a person believes they hold creative personality traits), and creative personal identity (the extent to which a person characterizes themselves as creative). These three aspects of self-report creativity correspond to three of the suggested four Ps in Rhodes's taxonomy, leaving out only creative press.

[Kaufman \(2019\)](#) took a different taxonomical approach, classifying self-report creativity measures into activities, process, beliefs, and evaluation. Activities measure a person's participation or achievement in creative activities. Process measures the extent to which a person assesses their creative processes. Beliefs measure the extent to which a person thinks about creativity, as well as their own creativity. Finally, evaluation measures the extent to which a person assesses their creative work in domain-general and domain-specific areas. The following subsections discuss the different types of creativity self-report measures using Kaufman's taxonomic approach.

Activities

Activity self-report measures ask individuals to report their creative achievements or engagement in creative activities. These types of measures range from assessing creativity at the everyday level to the eminent level, and assess either domain-specific creativity, domain-general creativity, or both. When reporting creative activity, participants can misinterpret engagement or achievement.

However, compared to other types of self-report creativity measures, reports of creative activities and accomplishments are argued to be less vulnerable to inflation and social desirability. Thus, this type of self-report measure is argued to be a more appropriate proxy for creative performance. Highlighted below are several self-report measures that assess creative activity.

[Holland \(1961\)](#) developed a 16-item checklist of scientific and artistic accomplishments assumed to require creative behavior (i.e., “invented a patentable device”; “won literary award or prize for creative writing”). Holland’s approach to assessing creative performance specifically involved asking individuals about public recognition in science and the arts (i.e., awards, prizes, publication). Holland’s checklist approach and recognition of domain specificity helped shape development of future activity self-reports (e.g., [Hocevar, 1979](#); [Milgram and Milgram, 1976](#)).

[Milgram and Milgram \(1976\)](#) developed an activity self-report measure, asking individuals to report on a variety of items describing accomplishments across nine domains: community service, dance, drama, fine arts, music, science, social leadership, sports, and writing. These items were presented to individuals in order from low quality accomplishments to high quality accomplishments in each domain. In addition to being more specified in terms of domains compared to [Holland \(1961\)](#), Milgram and Milgram’s measure also differed in scoring. Whereas frequencies are calculated for [Holland \(1961\)](#)’s measure, [Milgram and Milgram \(1976\)](#)’s measure can produce three scores: (1) a score for each *domain* an individual was involved in, (2) a score for each *activity* an individual was involved in, and (3) a weighted score dependent on sample responses that gave an individual a lower score for engaging in common activities and a higher score for engaging in rare activities.

[Hocevar \(1979\)](#)’s Creative Behavior Inventory (CBI) is another activity self-report measure similar to [Holland \(1961\)](#). The CBI asks individuals to report the extent to which they engage in 90 creative activities and accomplishments that range from everyday creativity (i.e., “made your own holiday decorations” and “designed a game”) to professional creativity (“entered a mathematical paper or project into contest” and “received an award for a performance in a popular dance”). The inventory covers a total of six domains: fine arts, crafts, literature, math and science, music, and performing arts. Additionally, there are 15 miscellaneous items that do not fit into a particular domain. In completing the inventory, participants are given the choice to respond “never”, “once or twice”, “3–5 times”, and “more than 5 times” to each item. Thus, unlike [Holland \(1961\)](#), the CBI asks individuals to report on a greater number of activities and accomplishments, and these activities and accomplishments are specified even further in terms of domain. Additionally, whereas [Holland \(1961\)](#) asks individuals to simply check the items that apply to them, [Hocevar \(1979\)](#) asks individuals to report on a scale ranging in engagement frequency (i.e., 3–5 times). For a shortened version of the CBI, see [Dollinger \(2003\)](#), who shortened the CBI scale to 28-items by removing items that asked about infrequent, high-level accomplishments.

[Batey \(2007\)](#)’s Biographical Inventory of Creative Behaviors (BICB) is another activity self-report measure. Unlike the previously mentioned activity self-report measures, the BICB assesses creativity at a general level. More specifically, the BICB asks participants to indicate whether or not they engaged in 34 everyday creative activities over the past 12 months (i.e., “written a short story”, “produced your own food recipes”, “selected to lead/manage others”, “made up a joke”, and “formed a sculpture using any suitable materials”). Because there are no subscale calculations for the BICB and because the items are categorical, the binary scores are computed to obtain an overall creativity score.

The Creative Achievement Questionnaire (CAQ) created by [Carson et al. \(2005\)](#) is an activity self-report measure that assesses creativity at the professional level and eminent level. The CAQ asks individuals to report their creative accomplishments in ten domains: visual arts, music, dance, architectural design, creative writing, humor, invention, science, theater and film, and culinary arts. Individuals are presented each domain and asked to place a checkmark beside the sentences that apply to them. The list of sentences range from having no training or recognized talent in the given area to having been nationally recognized in the given area. The CAQ does not only provide domain-specific creativity scores, but can also be scored to compute a total creative achievement score. However, the CAQ focuses on more professional level activities as opposed to everyday creative activities. As such, it tends to result in skewed distributions and may not be appropriate for many samples.

More recently, [Hoffmann et al. 2016](#) constructed a self-report creative behavior scale that assesses engagement in digital creativity in adolescents. Known as the Creative Behavior Questionnaire: Digital (CBQD), this measure asks participants to report the extent to which they engaged in 30 activities over the past three months, last year, and in their life (i.e., “created a podcast”, “made a music mash-up”, and “started a new blog”). Participants respond on a scale ranging from “never” to “4 or more times”.

Most of the measures identified here ask participants to evaluate the frequency in which they engage in a specific creative activity. Several of these measures also ask participants for specific accomplishments in multiple domains. As a result, these measures tend to be viewed as somewhat more objective than other self-report measures. However, it is important to note that these measures may not be appropriate for measuring creativity under certain circumstances. For example, asking about engaging in creative activities and accomplishments in music, art, or science, is likely not going to be relevant to understanding or predicting who will be a creative leader.

Process

Although most measures that assess creative processes are in the form of a divergent thinking task or creative problem solving task, some researchers created self-report approaches. These process-oriented self-report measures assess aspects such as ideational behavior, creative cognitive processes, and creative thinking styles – universal aspects of creativity that can be assessed regardless of an individual’s level of creativity and regardless of the creative domain. One challenge with process self-report measures is

that it may be difficult to assess cognitive processes that are automatic in nature. Additionally, of the four types of self-report measures, there are a limited number of process measures a researcher can choose from. Discussed below are three self-report measures that assess creative processes.

The Runco Ideation Behavior Scale (RIBS) developed by [Runco et al. \(2001\)](#) asks individuals to indicate the extent to which they exhibit appreciation of, use of, and skill of idea generation in their everyday life. The scale consists of 23 items that individuals respond to on a 5-point Likert-type scale ranging from “never” to “just about every day, sometimes more than once each day, etc.” Items include “sometimes I get so interested in a new idea that I forget about other things that I should be doing”, “I would take a college course which was based on original ideas”, and “I am good at combining ideas in ways that others have not tried.” More recently, the RIBS has been revised to include a 74-item long form (RIBS-V) and a 19-item short form (RIBS-S).

[Zhang and Bartol \(2010\)](#) also developed a self-report measure to assess creative processes. Known as the Creative Process Engagement scale, this measure asks individuals to indicate the extent to which they engage in problem identification, information searching and encoding, and idea generation. Items include “I decompose a difficult problem/assignment into parts to obtain greater understanding” (problem identification), “I retain large amounts of detailed information in my area of expertise for future use” (information searching and encoding), and “I generate a significant number of alternatives to the same problem before I choose the final solution” (idea generation). Individuals are asked to respond to these 11 items on a 5-point Likert-type scale ranging from “never” to “very frequently”.

The Innovative Work Behaviors (IWB) scale developed by [De Jong and Den Hartog \(2010\)](#) includes four processes that are of particular importance for creativity and innovation in the workplace. Specifically, the scale includes a subscale for idea generation (generates original solutions to work problems), idea exploration (pays attention to issues that are not part of his/her daily work), idea championing (convinces people to support innovative ideas), and idea implementation (contributes to the implementation of new ideas). This measure focuses not only on the idea generation aspect, but also idea implementation.

None of these measures fully cover the entire cycle of processes. The RIBS measure focuses exclusively on idea generation. The Creative Process Engagement scale covers the first three phases, but stops at idea generation. In contrast, the IWB starts with idea generation and then covers processes important for implementation, which are crucial for organizational innovation.

Beliefs

The beliefs category consists of measures that ask individuals to report on their values, motivations, and personality traits as they relate to creativity. Belief self-reports are more focused on the creative person, generally assessing domain-general creativity instead of domain-specific creativity. Unlike the other three types of self-report measures, belief self-reports encompass higher-order constructs (e.g., openness to experience). Although belief self-reports are typically used as predictor measures of creativity, they have also been used as a criterion, positing that individuals are aware of the subtleties of their creativity. Highlighted below are self-report measures that assess creative beliefs.

The Self-Assessment of Creativity Scale developed by [Kaufman and Baer \(2004\)](#) is a self-report creativity measure that taps into individuals’ beliefs. This measure asks individuals to indicate the extent to which they believe they are creative on items such as “I am good at coming up with new and different ideas” and “I consider myself to be very creative”.

Researchers commonly use the [Tierney and Farmer \(2002\)](#) Creative Self-Efficacy Scale to assess an individual’s belief in whether they are able to produce something creative (i.e., “I feel that I am good at generating novel ideas”). [Karwowski et al. \(2012\)](#) developed the Short Scale of Creative Self (SSCS), an 11-item, Likert-type scale that assesses creative self-efficacy using six items (i.e., “I am good at proposing original solutions to problems”) and creative personal identity using five items (i.e., “my creativity is important to who I am”).

Researchers also measure individual motivation as it relates to creativity. For example, the Creative Mindset Scale developed by [Karwowski \(2014\)](#) assesses an individual’s beliefs as to whether creative ability is fixed or malleable. The scale is composed of 10 items, five items that measure fixedness beliefs (i.e., “you either are creative or you are not – even trying very hard you cannot change much”) and five items that measure malleability beliefs (i.e., “practice makes perfect – perseverance and trying hard are the best ways to develop and expand one’s capabilities”).

It should be noted that while these measures evaluate creative self-beliefs, they are somewhat distinct in nature. As noted, these measures can be viewed as precursors or predictors of creativity, but have occasionally served as the construct of interest.

Evaluation

Scales that fall under the evaluation category are those that ask individuals to appraise their creativity against a normative standard. Evaluation self-report measures can ask individuals to evaluate their creativity overall or in a specific domain. Because evaluation self-report measures assess either domain-general or domain-specific creativity, the normative group seems to matter (e.g., when asked about creativity in the arts, rating yourself against artists vs. rating against the general population). This feature of evaluative self-reports accordingly highlights the importance of individuals being aware of their creative performance in comparison to others. Discussed below are self-report measures that assess creative evaluations.

Some creativity researchers have asked individuals to estimate their perceived overall creative ability on a bell curve, an adaptation of [Furnham and Gasson \(1998\)](#)’s self-report intelligence measure. To illustrate, individuals are presented with a depiction of

a bell curve illustrating a normal distribution of creativity scores. Individuals are informed that a mean score of 100 indicates average creativity, 70 indicates below-average creativity, and 130 indicates above-average creativity. Individuals are specifically asked to rate their creative ability using this information presented.

The Kaufman Domains of Creativity Scale (K-DOCS) (2012) is another scale that asks individuals to evaluate their creativity in a variety of domains. This scale is based on items from other previously developed scales such as Carson et al. (2005)'s CAQ and previous shorter iterations. More specifically, the K-DOCS instructs individuals to report how creative they are in 50 different creative acts compared to people that are around the test taker's age and level of life experience. Domains include artistic (i.e., "appreciating a beautiful painting"), mechanical/scientific (i.e., "taking apart machines and figuring out how they work"), music and writing performance (i.e., "learning how to play a musical instrument"), scholarly (i.e., "gathering the best possible assortment of articles or papers to support a specific point of view"), and self/everyday (i.e., "planning a trip or event with friends that meets everyone's needs"). Individuals rate themselves on a 5-point Likert-type scale ranging from "much less creative" to "much more creative".

Domain General Versus Domain Specific Measures

Creativity self-reports are particularly unique compared to other measures because their structure can assume either domain-general or domain-specificity. As mentioned, some self-report measures tend to be domain specific, focusing on measuring creativity in specific domains (e.g., K-DOCS). Other self-report measures tend to be domain general, such as measures of creative self-efficacy or bell curve. There are also self-report measures that evaluate specific domains, but also provide an overall score that is across multiple domains, such as the CAQ.

The debate as to whether creativity is domain-general or domain-specific further complicates creativity measurement. In other words, if an individual is creative in science, are they also creative in writing or art? Are "creative people" creative in general or in a specific domain? Take Walt Disney for example. Walt Disney has been deemed one of the most creative individuals of all time. Is Walt Disney creative in the field of entertainment alone or do people consider Walt Disney to be a creative person in general? Would Walt Disney have been able to execute the same level of creativity in other fields, such as science or sports?

Early creativity measures were typically crafted under the assumption that creativity was domain-general (e.g., divergent thinking tasks). However, over time, the domain-general assumption abated as evidence of domain-specificity emerged. Particularly with self-reports, researchers began finding that individuals tended to self-report different levels of creativity depending on the domain presented. That is, individuals believe they are more or less creative in some domains over others.

Strengths and Drawbacks of Creativity Self-Reports

As with any measure, there are strengths and drawbacks to self-report creativity. Self-report creativity measures are beneficial in that they are highly feasible and practical to use. Self-report creativity measures are typically free of charge, quick to administer, and easy to score. With the exception of some activity self-reports (e.g., CAQ, BICB), self-report creativity scales also yield high reliability. What is more, self-report creativity measures have face validity, which is an important feature for the practitioner sphere. Creativity self-reports have also demonstrated significant positive relationships with other creativity self-reports, divergent thinking measures, and scores on the Torrance Tests of Creative Thinking.

In comparison to other approaches to creativity measurement, self-reports have their strong points. For example, aside from internal biases, self-report measures do not introduce increased error in the form of outside raters compared to other measurement approaches (e.g., scoring divergent thinking tests, judgement of products, other-ratings). Additionally, self-reports can assess creativity at both the domain-general and/or domain-specific level, whereas other measures may be indicative of only one level (e.g., domain-specific creativity assessed in judgement of products, domain-general creativity assessed in creative problem-solving tasks).

However, researchers do stress issues that come with using creativity self-reports. For example, due to the face validity of self-report creativity measures, individuals may be cognizant of what is being asked of them, which can potentially bias results (e.g., individuals may feel inclined to respond in a socially desirable way). In contrast, individuals may not be aware of their beliefs or self-concepts as they relate to creativity, thereby leading to understated or inflated results rather than the obtainment of true estimates. Additionally, self-report creativity measures are considered more appropriate for low-stakes situations (e.g., research) rather than high stakes situations (e.g., selection in work or school setting). It is important to note that in high stakes situations, measures of personality may be utilized to assess creativity, among other personality traits.

Indeed, compared to other creativity measurement approaches (e.g., divergent thinking tests, judgement of products, ratings by peers, teachers, or supervisors), some researchers caution against the use of self-report measures as a criterion, indicating that self-reports may focus more on motivation to be creative and creative self-efficacy, and are not directly related to actual creative performance. However, some researchers posit self-report creativity measures are acceptable to use as a criterion measure, arguing that individuals are most likely aware of their levels of creativity and can thus report on it accurately. Others argue that if a self-report creativity measure were to be used as a criterion, measures of creative achievement are optimal because they seem less susceptible to exaggerations and social desirability.

Introduction

The relationship of medicine to creativity can be understood from historical and developmental perspectives. The current epistemological foundation of medicine is rational empiricism – an emphasis on phenomena that are measurable, quantitative and apprehended in a rational, analytical manner. Non-rational phenomena such as imagination, inspiration, and intuition – while important in the creative process – currently have an attenuated emphasis in medicine.

The emergence of rational empiricism in contemporary medicine can be traced historically. As discussed by Laurence Kirmayer (2006); 16th century Renaissance physicians such as Paracelsus placed imagination in a central role. According to Paracelsus all manifest phenomena - including those specific to medicine and healing - were understood as flowing from an act of creative imagination - an act that allowed trans-rational, celestial influences to impact upon the material world. But, foundational shifts occurred in medicine as western culture transitioned into the Enlightenment of the 17th and 18th centuries. Enlightenment thinkers were suspicious of any phenomena that could not be subjected to logic, reason and rational analysis. Non-rational phenomena such as the imagination were categorized a priori as irrational – without logic, reason and baseless – and imagination was rendered a groundless and illusory force. From the Enlightenment perspective the imagination became equated with the *imaginary* – the untrue, unreal and fanciful.

The countertrend to this diminishment of the imagination was represented by the emergence of Romanticism in the late 18th to mid-19th centuries. For the Romantics the non-rational force of the imagination surpassed conscious reason's ability to fully apprehend the depth of human experience. Ultimately, the tension between rationality and non-rationality contributed to a bifurcation between the arts and the sciences. In the sciences rational analysis and empirical proofs dominated, while in the arts non-rational phenomena such as imagination and inspiration were highly regarded and valued.

Western medicine developed in synchrony with these broader cultural trends and foundationally aligned itself with the sciences - adopting a singular focus on rationality. This alignment has endured. Over the past several decades it has been typified by the dominant position afforded evidence-based medicine (EBM). As stated by The Evidence-Based Medicine Working Group (1992) it: "de-emphasizes intuition, unsystematic clinical experience, and pathophysiological rationale as sufficient grounds for clinical decision making and stresses the examination of evidence from clinical research." EBM has made a substantial contribution by solidifying a rationally grounded scientific foundation for the practice of medicine. In addition, EBM is evolving - becoming more attuned to patient values, individual differences and clinical expertise. Yet the singular emphasis of EBM remains on rational processes, leaving it out of full alignment with the more complex processes that animate creative discovery. With regard to research, Desmond Sheridan and Desmond Julian noted the following:

Almost all research activity currently undertaken in support of EBM involves evaluations of existing evidence to determine the best available, usually in the form of systematic reviews, and this form of research has expanded greatly since the launch of EBM. This is quite different from original science, which seeks to explore and discover new knowledge (2016, p. 211).

In contrast to the singular, rational focus prominent in medicine, creativity is bimodal, and includes both rational and non-rational elements. The neuroscientists John Kounios and Mark Beeman (2015) provided support for this perspective by defining two distinct but interdependent modes operative in the creative process – a conscious, rational, *analytical* mode and an unconscious, non-rational, *insightful* mode. Kounios and Beeman described the analytical mode as one where solutions are arrived at in a rational

step-by-step manner. In contrast, the insightful mode is non-rational and is characterized by less linearity – a mode where solutions seem to appear spontaneously in a flash of insight. Their research provided evidence for the distinct neurophysiological features of these two modes of expression, and the ways they beneficially complement each other in the creative process.

The relative absence of an epistemology and methodology that includes non-rational processes served as an obstacle to the full development of creativity in medicine. [Roberta Ness \(2015a\)](#) – a leading creativity and medicine scholar – goes so far as to call the current situation a creativity crisis. While not primarily focused on historical and developmental factors, Ness has taken an unflinching approach to challenging the ways current individual, cultural, and institutional factors create an unfavorable balance away from creative innovation – and an attenuation of the creative dynamism needed for discovery.

In medicine the rational-empirical approach has the lasting advantage of emphasizing a rigorous, analytical methodology that guards against unsupported conceptualizations of disease processes and treatment strategies. But, the singular emphasis on rationality and the diminished appreciation for non-rational phenomena – such as intuition and imagination – simultaneously limits full engagement with the creative process. Notwithstanding this, the search for more effective ways to treat human affliction is a driving force and vitalizing element in the field of medicine, and creativity is fundamental to this endeavor. This article will discuss the creative process in medicine – both in the realm of the medical scientist and in the realm of the medical practitioner – with an eye to future developments that have the potential to increase creative capacity within the field.

Discovery - The Medical Scientist

The quest of the medical scientist is to discover new and better ways to treat disease and reduce human suffering. To support the process of medical discovery, a significant allocation of resources – both human and capital – is dedicated to this quest. Research America estimates that in 2017, in the United States alone, over 170 billion dollars were spent on medical and health research occupying 120,000 medical scientists.

[Morton Meyers \(2007\)](#) questioned whether this massive research enterprise is as rational and systematic as commonly assumed. Meyers chronicled a large number of significant medical discoveries and demonstrated that many were not made by painstaking experimentation, but rather by chance, or even by error. Confronting the notion that a singularly rational and empirical approach is the key to discovery, Meyers stated: “Rational thought can be applied only to what is known. All new ideas are generated with an irrational element in that there is no way to predict them” (2007, p. 6).

The example of Otto Loewi serves to illustrate the influence of non-rational phenomena in the creative process. Loewi discovered that communication between nerve cells was a chemical process – a discovery that laid the foundation for modern psychopharmacology. As an acknowledgment of the importance of this discovery, Loewi was awarded the Nobel Prize in physiology and medicine in 1936.

The inspiration that guided Loewi’s Nobel experiment came in 1920, in a dream – actually two dreams – as recounted by Loewi:

The night before Easter Sunday of that year I awoke, turned on the light, and jotted down a few notes on a tiny slip of paper. Then I fell asleep again. It occurred to me at six o’clock in the morning that during the night I had written down something most important, but I was unable to decipher the scrawl. The next night at three o’clock, the idea returned. It was the design of an experiment to determine whether or not the hypothesis of chemical transmission that I had uttered seventeen years ago was correct. I got up immediately, went to the laboratory, and performed a simple experiment on a frog heart according to the nocturnal design. (1960, p. 17)

Otto Loewi’s experience is consistent with [Graham Wallas’ \(1926\)](#) classic four stage model of the creative process. In Wallas’ model rational and non-rational modes of experience oscillate through four major stages: In the *preparation* stage conscious rational efforts are applied to acquire knowledge. Next, in the *incubation* stage – non-rational, unconscious processes ensue – supporting the development of insight and inspiration. Then, in the *illumination* stage creative ideas and inspirations, formed in the incubation stage, spontaneously emerge into consciousness. Lastly, in the *verification* stage conscious rational processes are re-engaged to evaluate the products of the illumination stage.

Transformative discoveries seldom, if ever, emerge without substantial preparation. Otto Loewi’s inspired dreams occurred in 1920. But, his medical studies were initiated in 1891, specific training in laboratory pharmacology started in 1898, and he began theoretical discussions regarding chemical neurotransmission in 1903. Hence, the conscious, rational, knowledge accumulating stage – the preparation that preceding his inspired dreams – extended over several decades. The incubation stage of Loewi’s discovery is difficult to define. As an unconscious and non-rational process incubation is more challenging to understand and demarcate in time. Yet, the notion of a period of incubation prior to creative emergence has significant empirical support ([Sio and Ormerod, 2009](#)), and the phenomenon of *unconscious work* – an associative process occurring outside of conscious awareness – has the best evidence as an explanatory mechanism ([Gilhooly, 2016](#)). It can only be inferred that the incubation phase of Loewi’s creative process took place in parallel with his extended period of preparation. In contrast to the prolonged preparation and incubation stages, the dreams that accounted for Loewi’s illumination stage occurred abruptly on two successive nights. Subsequently, several more decades of experimentation followed in the verification stage, to rationally analyze and validate the original findings.

Healing - The Medical Practitioner

Creative processes are also relevant in the day to day encounters between medical practitioners and their patients – encounters that number almost one billion per year in the U.S. alone. When spontaneous inspiration emerges for the medical scientist it is usually followed by a prolonged period of experimentation and verification. In contrast, creativity in the realm of the medical practitioner often takes on a greater immediacy, a more constricted time frame, and sometimes an urgency. For example, a colleague specializing in internal medicine - practicing at a major medical center - described the following experience:

The call from the resident awakened me at about 6:30 a.m. - acute myocardial infarction he suggested - while providing the results of mostly supportive investigations. He seemed sure, yet something seemed off. I felt a sense of uncertainty, anxiety, dis-ease – I don't usually feel this way anymore. I arrived at the hospital, examined the patient and continued to feel strange – anxious, stressed, uncertain – something is wrong. A respected consulting cardiologist concurred with the resident – myocardial infarction. Arrangements were made for immediate transfer and cardiac catheterization. My feelings of uncertainty and anxiety continued – they were not welcome but somehow I just let them be. The transfer of the patient to the cardiology unit was unfolding quickly - my anxiety persisted. Spontaneously, I asked the unit nurse to add an urgent thyroid screening test to the patient's blood work. The impulse came like an unformed thought, or more like a feeling, or a cluster of sensations, like a finger tapping me on the shoulder – a subtle something letting itself be known to me.¹

The findings of the screening test subsequently confirmed an acute thyroid abnormality. This physician's spontaneous inspiration radically altered the course of treatment. It occasioned a revision of the diagnosis and an alteration of the treatment plan that may well have saved the patient's life.

The study of diagnostic reasoning in medicine has drawn upon cognitive psychology and aligned with a dual process model that posits two modes of cognition: An analytical system that is rational and relies upon conscious thought, and a non-analytical system that is non-rational and relies on unconscious processes. The functioning of the non-analytical system is thought to be supported by pre-existing implicit knowledge, enhanced by experience, and reliant upon automatic pattern recognition. However, the non-analytical system's reliance upon unconscious processes is thought to render it prone to bias and error. This has led to an advocacy for training interventions designed to increase rational, analytical capacities, as safeguards against the error proneness of non-analytical cognition (Croskerry, 2013). There is value in pursuing strategies to increase the capacity for rational thinking and meta-cognition – the higher order awareness of one's thinking process – in medical practice. But, in relation to creativity, there is also a need for a more comprehensive understanding of non-rational processes, and the way they may support insight and inspiration.

The practitioner in the above vignette was inspired to order a thyroid screening test after several anxious hours of uncertainty. From the dual process perspective, neither rational analysis nor non-analytical pattern recognition is sufficient to fully account for the phenomena described. Rather, the vignette is better understood from the perspective of Wallas' previously described model of the creative process: The practitioner in this vignette has a substantial preparatory foundation. She is trained, experienced, and functions at an expert level. When the case was presented she recognized an immediate unsettledness – an intuition. Phenomenologically, intuition is distinct from creativity but related - commonly presenting as a vague anticipatory perception that serves to guide idea generation (Petervari et al., 2016). The practitioner reports staying with the experience of unsettledness while it persisted for several hours - presumably supporting the non-rational work of unconscious incubation. Then, the inspiration to order the laboratory test abruptly emerged into consciousness. The abrupt emergence of the insight phenomenologically distinguishes it from analytical thinking which is slow and deliberate - whereas insight comes in a flash. Also the quality of the insight has the clear sense of newness – a fresh idea. This is distinct from pattern recognition - which is the application of old and established information superimposed on a current situation. Then, in a return to rational cognition, the diagnosis was subsequently verified by analysis of the laboratory test.

While the vignette is anecdotal, and the understanding offered conjectural, it phenomenologically aligns with established models of the creative process. This invites a more nuanced application of the dual process model - and further inquiry into the manifestations of creativity in medical practice. Focused inquiry into creativity in medicine is not common, but there has been some nascent interest in related areas. For instance, Oliva et al. (2016) studied the impact of *gut feelings* in the diagnostic process in general practitioners – intuitive sensibilities that provide information in a non-rational manner. The group of physicians they studied reported using intuitive feelings commonly and effectively in their day to day work with patients. The authors further suggested that the ability to integrate non-analytical processes into clinical decision-making – along with rational, analytical, evidence based practice – is characteristic of advanced learning.

In considering the potential contributions of creativity to the practice of medicine Paul Haidet (2007) provided the useful analogy of jazz improvisation. Fundamental to advanced jazz performance is the ability to creatively improvise – to simultaneously compose and perform – an integration of rational and non-rational processes (Beatty and Jung, 2018). A long process of learning musical language is required prior to developing the capacity for jazz improvisation. Similarly in medicine, many years of preparation are needed to acquire the foundational knowledge necessary for practice. But then physicians are also potentially tasked with developing improvisational skills – advanced skills that allow them to creatively apply themselves to the clinical encounter – to

¹This clinical vignette was used with the permission of Jillian Horton, M.D.

spontaneously improvise in a manner that is attuned to the patient, clinical situation, and context. Some practitioners develop such skills organically as they progress toward mastery, but the therapeutic impact of these skills is rarely a focus of serious study, and support for their development is uncommon.

Pre-rationality, Rationality, Arationality

The philosopher [Jean Gebser \(1983\)](#) has meticulously and extensively provided cultural and historical evidence for the evolution of western consciousness through discrete developmental stages. From Gebser's perspective, mental-rational consciousness is currently the most prevalent method of apprehending the world. It is a perspective reliant on a structure of consciousness with the capacity for analytical thinking – the ability to apply sequential logic, linear causality and critical cognition. It relies upon empirical methods for knowledge acquisition – it is *rational*. The emergence of this form of apprehension is evident in the shift to Enlightenment thinking in the 17th and 18th centuries. While Gebser acknowledged that contemporary people do not consistently function rationally he would posit that most are capable of drawing upon this capacity. Gebser also observed that while the mental-rational structure affords considerable benefits – such as the rational empirical approach that is the foundation for the scientific method – it also can become deficient. For instance, when the open inquiry of science constricts into scientism – the fundamentalist belief that rational and empirical knowledge is the only valid form of knowledge.

The notion of non-rationality is more complex as it is not a unitary concept. In Gebser's model the structures of consciousness that historically and developmentally precede the mental-rational structure can be considered *pre-rational* – they do not yet possess the capacity for rational cognition. Phenomena important in the creative process such as dreams, intuition and imagination are in this category. But, rather than rendering these modes irrelevant, Gebser proposed that their integration is fundamental to a new and emerging consciousness structure – a structure he labeled *integral*. The integral structure integrates all previous consciousness structures. It is also non-rational but is clearly distinct from pre-rational structures because it includes the mental rational structure. Gebser described this structure as *arational* – indicating a more comprehensive mode of awareness – an awareness that is informed by all previous consciousness structures. As such, the integral structure maintains the benefits of rationality, while seeing through the exclusivity of the rational perspective. In his analysis Gebser provided extensive examples of the emergence of this structure, as it is manifesting across diverse fields of human endeavor.

As it relates to creativity, Gebser's integrative phenomenological perspective is in accord with emerging evidence from the neurosciences. For example, the neuroscientists [Roger Beaty and Rex Jung \(2018\)](#) have studied creative cognition – with an emphasis on understanding the neural mechanisms underlying creativity in general – and artistic improvisation in particular. Their work focused on the relationship between the brain's default mode network and the brain's executive control network – two large-scale neural networks. The default mode is a network of mid-line and inferior parietal brain sites that are active when the brain is engaged in non-rational processes such as mind wandering, imagining and dreaming. In contrast, the executive control network, which includes the dorsolateral pre-frontal cortex as a core hub, is engaged during tasks requiring externally directed attention, and supports rational processes such as executive functions, cognitive control and conscious decision making. These two networks have been considered to have an anti-correlated relationship – engagement with one suppresses activity in the other. However, [Beaty and Jung \(2018\)](#) present evidence of coordinated activity between these two networks in creative activities such as improvisation – providing neurological support for the notion that integration of rational and non-rational processes is important in creative processes (see Neuroscience: The Cerebellum).

Operationalizing the preceding theoretical constructs, [Richard Szuster \(2018\)](#) has provided preliminary evidence demonstrating that deliberate efforts to integrate rational and non-rational elements can facilitate the creative process. In a naturalistic study using Embodied Imagination – a method of working with dreams and the imagination pioneered by [Robert Bosnak \(2007\)](#) – normal waking consciousness was activated concurrent with dream-like consciousness. After the intervention, study participants reported a re-enlivening of their creative processes and increases in their creative productivity. Additionally, an electroencephalograph was employed to investigate the neurophysiology present during the Embodied Imagination session. Analysis demonstrated a more integrated brainwave pattern in study participants during the session – where frequencies typical of normal waking were present in a more balanced relationship to frequencies typical of dreaming. These findings suggest that the increased creative productivity reported by study participants was associated with a measurable and replicable neurophysiological state – a state of mind that was evoked by the concurrent presence of rational and non-rational processes.

The net result of the aforementioned is the emerging notion that the creative process can be supported by a creative mind state – a mind state that is aligned with a developmental capacity for integration of rational and non-rational processes. Contributions from the neurosciences are beginning to provide further support for this perspective, suggesting that the capacity for this form of creativity – expressed at a phenomenological level – has distinct correlates at a neurological level.

The Creative Mind in Medicine

The frequently referenced touchstone – “chance favors the prepared mind” – was articulated by Louis Pasteur, the great French microbiologist and pioneer of the germ theory of disease. It suggests that flashes of insight, the foundation for creative discoveries, do not just happen, but are facilitated by preparation. In medicine, preparation emphasizes empirical knowledge – being fully informed of

the pre-existing scientific evidence base – a conscious, rational form of knowing. This form of preparation is necessary, valuable and fundamental in medicine but - as previously noted regarding the creative process - it is partial. What follows are examples of efforts to facilitate the creative process in medicine by expanding beyond an exclusive focus on rational, linear, analytic processes and implementing additional forms of preparation.

Unmasking Genius: Cognitive Tools to Enhance Creativity

Roberta Ness (2011, 2013) has been a leading advocate for the development of creative capacity within the medical sciences. Drawing upon effective creativity training programs in education and business - and her own research into the lives of highly creative individuals - she created the *Innovative Thinking* program for the health sciences. In this program Ness outlined a set of cognitive skills that can be taught and learned in the interest of increasing creative capacity. Included in the Innovative Thinking teaching curriculum are cognitive tools such as: broadening problems, narrowing perspectives, reversing assumptions, using analogy, and brainstorming - all taught with the goal of improving observational skills, facilitating creative inspiration, and supporting the generation of original ideas. Students completing the program demonstrated substantial increases in creative thinking, as measured on a standardized test of idea fluency and originality (Ness, 2015b).

A particular focus of Ness' program is developing the capacity to "think outside the box." This skill addresses the habitual tendency to be constrained by pre-existing mental constructs and patterns – patterns that Ness labels *frames*. Frames are static assumptions and expectations based upon past learning. While frames allow for the efficient application of pre-established knowledge, they restrict the understanding of new information – automatically accommodating new information to established perspectives that conform to pre-existing conceptualizations and mental structures.

Consider the 'frame-breaking' example of Robin Warren - who was awarded the Nobel Prize in Medicine in 2005: In 1979 the idea that stomach ulcers were a result of excess stomach acid was a well-established dogma in medicine – a pre-existing frame. A large body of clinical literature supported this notion and a system of treatment was built around this dogma. Some of the medications designed to reduce stomach acid eventually became the world's biggest selling prescription drugs. Into this environment Robin Warren, an unknown Australian pathologist, presented the audacious idea that stomach ulcers were caused by a bacterial infection, not excess stomach acid.

Robin Warren's discovery began on an ordinary afternoon in 1979 while working in the pathology laboratory of the Royal Perth Hospital. Warren was at his microscope routinely examining a gastric biopsy sample – a sample of stomach tissue routinely taken to confirm the diagnosis of a stomach ulcer. As expected, he noted the sample to have changes consistent with chronic gastritis – an inflammation of the lining of the stomach.

But, on that day in 1979, Warren thought he could discern a faint bluish line in the sample. The line drew his attention and piqued his curiosity. Higher magnification unexpectedly showed the line to be composed of bacilli, a rod shaped form of bacterium – a contradiction to another pre-existing frame - that bacteria could not exist in the acidic environment of the stomach. Warren wondered if bacterial growth might be important in the formation of stomach ulcers – a novel, provocative and frame-breaking idea. It took years of rejection, ridicule of the idea, and the association with an energetic young colleague named Barry Marshall, before Warren was found to be correct. This discovery eventually led to a radically altered understanding of the cause of stomach ulcers, a revolution in treatment, and a Nobel Prize in Medicine.

The process of Warren's discovery is consistent with the frame-breaking strategies emphasized in Roberta Ness' Innovative Thinking program. Warren's discovery depended upon a capacity for observation that was not constrained by the prevailing frame – a frame that had limited the perception of thousands of other pathologists – who had examined many thousands of samples similar to Warren's – but were unable to see what Warren saw.

Mindful Practice: Creative Mind – Beginners Mind

The Innovative Thinking program, described in the previous section, has a concentrated focus on developing cognitive skills and creative thought. This section describes *Mindful Practice*, a more broadly focused program that - while not specifically focused on creativity - is exemplary of the integrative phenomena that are fundamental to the creative process. The program was designed by Ronald Epstein and Michael Krasner (2017) and employs elements such as narrative medicine, appreciative inquiry and contemplative practices to support the development of exemplary practitioners. The Mindful Practice program has been associated with an increased capacity for mindfulness, enhanced physician wellbeing, and improved attitudes associated with patient-centered care (Krasner et al., 2009).

Mindful Practice employs processes that are known to enhance creative potential. For instance, open monitoring meditation – a practice in which an open, allowing, and nonjudgmental attitude is cultivated toward whatever phenomena are arising in awareness – has been shown to be associated with increased creativity (Baas et al., 2014). Open monitoring meditation facilitates an ability to be non-reactively present from moment to moment, while simultaneously maintaining a discriminating awareness. This form of meditation has also been shown to activate the brain's default mode network sites concurrently with the executive control network sites (Marzetti et al., 2014) – similar to Beaty and Jung (2018) findings with creative improvisation in the arts. As such, open monitoring meditation can be understood as an integrating practice – a creative practice – that concurrently activates brain networks responsible for rational and non-rational modes of experience.

Contemplative practices such as open monitoring meditation support the development of *beginner's mind*. Beginner's mind is a concept introduced to western audiences by the Zen Buddhist teacher [Shunryu Suzuki \(1987\)](#), and to medical practice by [Ronald Epstein \(1999\)](#). In Suzuki's words: "If your mind is empty, it is always ready for anything; it is open to everything. In beginner's mind there are many possibilities; in expert's mind there are few" (1987, p. 1). Beginner's mind is the cultivated naiveté of the expert – it possesses the capacity to remain open to new possibilities, a mind that can encounter phenomenon with a freshness that is not restricted by pre-existing mental concepts – it is inherently a creative mind (see Zen Meditation).

Fundamental to the development of beginner's mind – and also supported by contemplative practice – is an increased capacity for *presence*. Presence indicates an experience of being engaged with the present moment. Presence includes an increased capacity for perception directed toward the various experiential states that are arising in moment to moment experience. Presence is not a binary concept but a directional one, with greater or lesser degrees possible. The more present we are, the more our experience is palpable, concrete, vivid and exact. The more present we are, the more deeply we are in touch with and vivified by our experience. In accord with the previously discussed analogy of jazz offered by Paul Haidet, presence supports an attunement to the circumstances unfolding in the moment. It supports spontaneity – a greater capacity for creative improvisation in the unfolding immediacy of medical practice. Mindful presence also allows for more deeply engaged interactions with patients. [David Rakel \(2018\)](#) provided evidence for the beneficial impacts of empathic presence on biomedical treatment, suggesting that presence not only supports creative improvisation in the interaction between practitioner and patient, but also directly supports healing.

The practice of medicine is a multi-leveled and multi-dimensional undertaking. The manner in which creativity manifests in the midst of this complexity defies simple categorization. The Mindful Practice program employs strategies that are known to increase creative potential and have also been shown to effect a concurrent activation of the neural networks responsible for rational and non-rational processes. This supports the notion that Mindful Practice facilitates an integrative process that is fundamental to some forms of creativity. However, it is important to note that the creative impacts described in this section have been demonstrated in controlled laboratory settings. An understanding of the impacts in naturalistic settings – such as medical research and medical practice – requires investigation and represents an important, and only beginning, area of inquiry.

Conclusion

Creativity is important to the field of medicine, potentially adding vitality to both the pursuit of discovery and the practice of healing. The epistemological foundation for contemporary medicine is rational empiricism – a unimodal perspective that assures a rational, scientific approach to the acquisition of knowledge and guards against the assimilation of unproven conceptualizations and fanciful beliefs. However, creativity is a bimodal process that includes both rational and non-rational elements. A sole reliance on rational empiricism limits the inclusion of non-rational elements, such as intuition and imagination, and impedes a full engagement with the creative process. In medicine, the disunity between rationality and non-rationality cannot be resolved by suppression of either, but rather by integration of both. The emerging evidence presented in this article suggests that this integration has the potential to enable a creative state of mind, that maintains the benefits of rational empiricism, while providing a more optimal platform for scientific discovery and the practice of healing.

There are many ways to define memory. Memory can refer to the remembering of facts or bits of general knowledge (semantic memory) or the recollection of personal experiences (episodic memory). It can refer to a process that is largely conscious (explicit memory) or one that is largely unconscious (implicit memory) such as the influence of prior experience on thought and behavior. It can be measured over short or long periods of time, and it can reflect performance on anything from skilled motor tasks to the free recall of complicated text passages. The multifariousness of memory makes it difficult to discuss in the context of its relationship to creativity because different aspects of memory are likely to have very different effects on creativity (which itself is far from a unitary construct). The current entry will discuss a few of the many ways in which research has explored the intersection between memory and creativity.

Prior Knowledge and Mental Fixation

Novelty is a central property of creativity. To be creative something must be new or different from what came before. Most creative ideas, however, do not come out of thin air. Rather, they are built upon and in the context of existing knowledge and ideas. As Isaac Newton is often quoted if he has “seen further it is by standing on the shoulders of giants.” Information in semantic memory (accumulated general knowledge of facts, ideas, and concepts) provides an important foundation upon which to explore novel ideas and solutions. Domain expertise is critical for creative thinking, allowing people to develop novel ideas by flexibly integrating and extending upon already known ideas. It is not typical for creative contributions and innovations in art and science to occur, for example, without at least some prerequisite knowledge in the subject matter.

There are instances, however, in which having too much prior knowledge can impede creativity, such as when one needs to think in ways that differ fundamentally from what is already known or established. In such instances, creativity may require the generation of non-obvious ideas or solutions, and domain expertise and information in memory can serve as an impediment to creativity by causing a phenomenon known as mental fixation. Mental fixation, which has been studied extensively in research on creative cognition, can be defined as the limiting or constraining effect of existing knowledge or behaviors on the successful completion of some cognitive process, such as the ability to remember, solve problems, or generate new ideas.

As discussed in more detail below, prior knowledge about a topic often takes the form of a schema or gist-based representation. Although synthesizing information into schemas may speed processing and allow people to navigate their information-heavy world without getting slowed down by unnecessary details (and can in many instances benefit creativity), it can also oversimplify thinking and constrain thought. For example, people tend to think about how to use objects as they are intended (e.g., a hammer is for hammering nails, not breaking a window) because that is how they have been used in the past. Such functional fixedness makes it difficult to produce new uses for objects due to the accumulation of experience with those objects. A classic demonstration of functional fixedness comes from [Maier's \(1931\)](#) two-string problem. In this problem, the goal is to join two strings suspended from the ceiling at opposite ends of a room separated by more than an arm span's length. There are a few items available in the room including a pair of pliers. What is the solution? Tie the pliers to one of the strings and use its weight as a pendulum to help draw the string toward you while holding the other. Participants often fail to generate this solution, presumably because they are biased to think only of the pliers' more typical function.

The use of schematic knowledge representations allows people to fill in the details based on what they already know, but when trying to think of something new and creative they find themselves unable to do so. Indeed, when trying to generate new ideas, people tend to rely on a retrieval-based strategy in which they attempt to retrieve existing ideas. An example of this comes from the Alternate Uses Task (AUT) in which the goal is to generate unusual uses of common objects such as a car tire. There are many familiar and dominant functions associated with car tires (e.g., making vehicles move, using them as tire swings) and ready

access to these associations often confines thinking to these obvious ideas at the expense of trying more novel approaches (using the car tire to construct a chandelier). Much of this is a natural result of the structure of long-term memory. When given a cue in the form of a creative prompt, the information that comes to mind most readily tends to be the most frequent or obvious. It is often only later in the idea generation process that more original ideas begin to emerge.

People often rely on examples and prior knowledge without even realizing it. Indeed, explicit instructions to deviate from old and existing ideas in a creative generation task are often ineffective at reducing mental fixation, with participants continuing to rely on examples or existing knowledge stored in memory. In one study by Smith et al. (1993), for example, participants were asked to draw pictures of never-before-seen alien creatures. Participants exposed to examples of alien creatures were more likely to incorporate features of the examples (i.e., four legs, a tail, antennae) than participants not exposed to the examples. Critically, this effect emerged even if participants were explicitly instructed to draw new alien creatures that diverged as much as possible from the examples. Presumably, after integrating the example aliens with the problem space, participants were unable to branch away from them even when they had the intention to do so.

For better or worse, people use examples and old ideas in their creative generations. Although such reliance may be helpful in some instances by jumpstarting the creative process, it can also be detrimental when old ideas and examples are flawed or when the goal is to be as novel or divergent as possible. Moreover, domain expertise can exacerbate the situation when the solution to a given problem or the optimal to-be-generated idea does not come from that domain. In a study by Wiley (1998), for example, baseball experts and novices attempted to solve Remote Associate Test (RAT) problems. RAT problems involve presenting participants with three seemingly unrelated cue words (e.g., plate, broken, shot) and asking them to try to come up with a fourth word that is related to each of the three cue words (solution: glass). In this case, some of the problem words were baseball-related (plate), but the solutions were not. The baseball experts had more difficulty solving the problems than the novices, presumably because their knowledge of baseball-related information constrained their search space, thus making the generation of appropriate associates from memory more difficult.

Analogical Transfer

Existing knowledge can also play a role in creativity through the use of analogical transfer. Two situations are analogous when they share common underlying principles despite superficially being dissimilar. For example, compare the functioning of the cells of the body to factories. Although cells are superficially dissimilar from factories (e.g., factories are built out of bricks whereas cells are not), both share a set of abstract relations. In both systems, resources are brought in and processed by specialized units across separate stages in a regulated fashion to generate products. Indeed, much work on creativity has been dedicated to understanding how innovations in technology can be inspired by nature (i.e., biomimicry). Sometimes people can solve problems via analogy, with analogical transfer argued to occur when a person uses a known source situation to solve an analogous, but often dissimilar appearing, target problem.

Analogies have the potential to serve as powerful sources of insightful and creative solutions. To illustrate, consider a laboratory paradigm used to study analogical transfer (Gick and Holyoak, 1983). In the first phase, participants read a story about a general attempting to capture a fortress. The general has a large army, and several roads lead to the fortress from all directions. His army could march down any of the roads, but landmines would mean that the weight of his army would detonate the mines, destroying his army and the surrounding countryside. A smaller force would not detonate the mines but would also not be sufficient to capture the fortress. The general's solution is to divide his army into smaller groups positioned at the head of each road and send them marching toward the fortress at the same time. In this manner, the smaller forces do not detonate the mines, and they simultaneously converge upon the fortress which they overtake. In the second phase, participants encounter a problem involving a doctor attempting to treat a patient with an inoperable stomach tumor. There is a kind of ray that can destroy the tumor when of sufficiently high intensity. At this intensity, however, it would also destroy much of the healthy tissue surrounding the tumor. A lower intensity would spare the healthy tissue but fail to destroy the tumor. What might the doctor do? Participants can easily devise a solution if they notice the relevance of the convergence solution from the fortress story: deploy multiple low-intensity rays arranged around the patient and direct them simultaneously toward the tumor. In this manner, the low-intensity rays spare the healthy tissue as they pass through, but when they converge upon the tumor, their summed intensity is sufficient to destroy the tumor.

These two stories share a common, underlying solution structure despite their distinct contexts, and if people first encounter the fortress problem, they tend to be more likely to solve the ray problem. Interestingly, however, the solution rate is still rather low unless participants are given an explicit hint to think back to the fortress story. That is, even if participants sufficiently encode the information from the first phase of the experiment, they often fail to spontaneously realize the connection to the second phase of the experiment. This finding suggests that people do not readily use structural information (e.g., the similar divide-and-conquer strategies underlying each problem) during retrieval, but rather, that they tend to rely on surface-level information (e.g., a medical vs. a war scenario). A major goal in many creative problem-solving contexts is to get people to spontaneously notice the deeper, structure-level connections that enable clever solutions. To do this often requires shifting focus away from superficial details and toward more abstract, generalizable concepts. Memory retrieval is a highly limited and cue-dependent process, however, and the requirement to get away from the strongest or most pre-potent responses to the cues that are currently available can be a significant challenge. Said differently, what someone can retrieve at a given moment or on a given task is severely limited by the context and cues that are available—a limit that constrains not only memory but analogical transfer and creative thinking more generally.

Research has shown, however, that analogical transfer can be facilitated either when sources are encoded at a more abstract level (that will more easily generalize to new situations) or when people are led to think about the deeper structure of a problem while trying to solve it (see Analogies).

The Benefits of Forgetting

Many people lament that they have such a terrible memory because they forget so much of what they want to remember. The ability to forget, however, is an important and adaptive component of the memory system. Forgetting helps keep memory up to date by ensuring that old and outdated information does not interfere with the learning and accessibility of more current and relevant information. Beyond that, forgetting has been shown to facilitate the ability to think creatively (Ditta and Storm, 2018), such as in the case of incubation effects where taking a break after a failed problem-solving attempt (i.e., an incubation period) can make someone more likely to solve that problem during their second problem-solving attempt (Sio and Rudowicz, 2007). Various mechanisms have been argued to underlie the incubation effect. According to the forgetting-fixation hypothesis, taking a break allows for the forgetting of the information that caused fixation during the first problem-solving attempt. Presumably, when problem solvers make unsuccessful attempts at solving a problem, they increase the memory accessibility of fixating information that is unhelpful, thus blocking access to the target solution. Taking a break allows for the fixating information to be forgotten, thereby freeing the person to retrieve or generate the target solution (Smith, 1995).

It is important to emphasize that when memory researchers talk about forgetting they are typically not talking about a permanent loss of availability or storage strength, but rather a temporary loss in accessibility or retrieval strength. This distinction is critical both for the adaptive functioning of memory and in considering the role of forgetting in creativity. By making old and outdated information temporarily inaccessible, forgetting as a mechanism of reduced accessibility can mitigate mental fixation and allow people to think of new and creative solutions. By retaining the storage strength of forgotten information, however, such information can be recovered should it become relevant to solving a new problem or thinking of a new creative idea. In this way, forgetting as a loss of retrieval strength but not a loss of storage strength has the potential to benefit creativity both in the near and long-term.

Retrieval Inhibition and Executive Control

In the case of incubation effects, forgetting is thought to occur as the result of the passage of time or as the result of a change in context, reducing the heightened accessibility of whatever information was causing mental fixation and impeding performance. Research has suggested, however, that there may also be inhibitory mechanisms in memory that can help people overcome fixation. Attempting to generate target associates on the RAT, for example, has been shown to cause the forgetting of the non-target associates that initially impeded performance. Likewise, attempting to think of new uses for an object in the AUT has been shown to cause the forgetting of previously encountered and generated uses. Importantly, individuals who exhibit larger effects of forgetting in these and other contexts tend to outperform on tasks of creativity, suggesting that this type of inhibitory or goal-directed forgetting is not just a side-effect of creative thinking but that it may play an adaptive role in the process of creative thinking (Storm and Patel, 2014).

The idea that inhibition might be helpful for creativity may seem at odds with the popular belief that creative individuals tend to be uninhibited geniuses that are more prone to mental disorders and substance abuse. Indeed, research has also observed a positive relationship between disinhibition and creativity (Carson, 2014). In some studies, individuals with inhibitory deficits have outperformed individuals without such deficits and, in other studies, individuals without inhibitory deficits have performed better on a creativity task when their inhibitory abilities were temporarily reduced (e.g., by drinking cranberry vodkas). These kinds of benefits of disinhibition tend to be observed on tasks where it is advantageous not to be constrained or limited by common assumptions or the need to cohere to some set of rules or boundaries. A lack of inhibition may also be helpful in that it allows people's thoughts to drift away from the task at hand in the form of mind wandering. Mind wandering may benefit creativity by leading to a change in context or to a reduction in mental fixation that allows people to generate new ideas and make new connections in ways that they would not have been able to do otherwise. More generally, there is evidence that thinking of distantly-related analogies, or just doing something different, can facilitate creativity, presumably because it helps people overcome the limits of their current way of thinking.

Taken together, the finding that both inhibition and disinhibition can relate positively to creativity is consistent with the idea that the ability to flexibly engage executive control may be more related to creative thinking than either process alone. Indeed, recent neuroimaging work on the default mode network and the executive control network has shown increased co-activation of these networks in individuals who display high levels of creative thinking (Beaty et al., 2015). In the context of overcoming mental fixation, it may be useful to inhibit and forget the sources of fixation, a process that requires executive control. In other contexts, however, where one may want to be flexible in their thinking, it may be beneficial to consider everything, a process that would require a loosening of executive control. Indeed, the ability to take advantage of inhibition when it is helpful and then diminish it when it is not may be one of the hallmarks of a memory system that is designed to facilitate creativity.

It is also important to consider task dynamics when thinking about the role of inhibition and executive control in creative problem-solving. Take the case of insight problems, which are set up in such a way to cause problem-solvers to reach a point of

impasse by leading them to form an inappropriate initial representation of a problem (often caused by prior experience). Solving insight problems often requires people to shift or restructure the way they think about the problem. In matchstick problems, for example, the goal is to move a single match from an incorrect equation to make a correct equation, such as changing $XIII + I = XI$ to $XIII - I = XII$. Many people neglect to use the matchsticks in the “+” sign because they consider it to be an unbreakable unit, thus failing to produce the correct solution. Unlike analytical problems, which involve approaching the solution in incremental steps, insight problems involve generating the solution suddenly after a period of impasse. Whereas executive control may be useful for facilitating the formation of a problem representation and working through the initial search space, it may not be helpful for achieving the kind of spontaneous restructuring processes that are required to overcome impasse. Indeed, in some situations it may even serve as an impediment to restructuring, keeping the problem-solver locked in the state of impasse that they need to escape.

Collaborative Inhibition

When it comes to memory and creativity, working with others is not always the best option. In the context of memory, research has shown that when people work together to remember the same information, they tend to recall less than they would have recalled had they worked independently and pooled their outputs. This effect, known as collaborative inhibition, is thought to occur because each individual utilizes their own memory system and personal retrieval techniques to store and recall information, and listening to other people recall information in a group situation disrupts these processes (Rajaram and Pereira-Pasarin, 2010). Hearing others’ output may also result in fixation on that information at the expense of recalling more of the unrecalled information, a phenomenon similar to part-set cuing.

Similar mechanisms are at play when people try to create together. Several studies on brainstorming in groups have found that output suffers when people collaborate to produce ideas. Such limiting effects likely occur because each person’s output interferes with others’ output, and people cannot keep track of the volume of ideas being shared. One particular study on group brainstorming found that being exposed to other people’s ideas reduced the number of different search areas that were explored, though the number of ideas produced in groups was comparable to the number of ideas that individuals generated. Additionally, people’s ideas tended to conform to the ideas being shared in the group (Kohn and Smith, 2011). Research has explored conditions that help reduce the interfering effects of group brainstorming, with the goal of making collaboration more effective, such as by having each individual generate their own ideas before coming together as a group to share those ideas.

Gist-Based Schemas and the Role of Memory Errors

Memory does not work by encoding verbatim bits of information like a computer or digital camera. Rather, it works by encoding experiences into gist-based schemas that allow people to think and make decisions more quickly and integrate new information with existing information in a way that often leads to a more accurate representation of what happened in the past and what will happen in the future. By encoding memories in the form of gist-based schemas, however, the way people remember can become vulnerable to distortion and bias, often leading them to recall things in a way that fits their general ideas or beliefs about what happened instead of what actually happened. This aspect of memory has important implications for creativity. Indeed, thinking of new ideas and creative solutions often requires the ability to synthesize and integrate information rather than compare and contrast isolated details. To benefit from prior experiences in the form of analogical transfer (discussed earlier), for example, one must be able to see the deeper underlying similarities between two situations and not just the superficial details.

Schemas can also serve as useful starting points from which to build upon what one already knows and implicitly incorporate new information that may be relevant to solving ongoing problems. When someone fails to solve a problem initially, they may set up a sort of web or trap to capture information that might be relevant to solving that problem in the future. To be effective, however, this process needs to be flexible and make connections that fit the gist of what is needed rather than something specific. In most creative contexts, after all, one rarely knows exactly what they are looking for. Given these considerations, it may not be surprising that people who are more susceptible to gist-based false memories (as demonstrated on the Deese/Roediger-McDermott task, in which participants study lists of words such as sour, candy, sugar, etc. for a later recognition test that contains critical lure words that are related to the list but were never actually presented, e.g., sweet), tend to perform better on RAT problems than participants who are less susceptible to gist-based false memories.

Constructive Processes in Episodic Memory

People rely on their imagination to simulate possible future or hypothetical events that are vivid and full of detail. In some sense, this type of mental simulation is an inherently creative act in that it involves imaging novel scenarios that have not yet occurred or that are unlikely ever to occur. People can engage in a sort of mental time travel that not only takes them back to the recent and distant past but the immediate and distant future. Evidence indicates a great deal of overlap between the cognitive and neural processes supporting remembering of past events and mentally simulating future events (Schacter et al., 2007). In this way, the

processes of episodic memory are decisively constructive, not reproductive—retrieval does not involve a verbatim replay of past events; rather, it involves the pulling together of various sources of information and experiences to recreate past experiences. Thus, according to the constructive episodic simulation hypothesis, episodic memory plays a key role not only in the recollection of the past but in the simulation of the future. People can flexibly recombine elements of past experiences in a way that supports the simulation of new and unexperienced scenarios. This process is not unlike those involved in creative brainstorming where one tries to imagine novel possibilities and solutions by recombining elements of existing knowledge and solutions. In this manner, the construction of episodically specific events may play a key role in the generation of creative ideas.

Recent evidence suggests that temporarily boosting the specificity of the episodic memory system through an episodic-specificity induction task can increase creative performance (Madore et al., 2015). In these experiments, participants who received the induction task were shown a brief video clip and then guided through a structured interview in which they were asked to recall as many specific details about the events of the video as possible. Participants in a control group watched the same video but were only asked to provide their general impressions. Creativity was tested in a later phase by having all participants try to think of unusual and creative uses of common objects (e.g., a newspaper). Compared to participants in the control group, participants in the episodic-induction group generated a greater variety of novel uses. When prompted to describe an imagined future event that could happen to them, participants in the episodic-induction group also included relatively more detail in their descriptions, thus showing that the manipulation boosted not only the variety of uses on the AUT, but the level of detail used when imagining the future. These and other results suggest that a common set of mechanisms may underlie episodic retrieval, future simulation, and creative generation.

Sleep, Memory, and Creativity

Anecdotal descriptions of sleep-induced insight are common, both among the general population and among famous scientists and artists. (see Dreams) Many people have reported going to bed at night only to find their problem solved or a creative idea sprung to life by the time they wake up in the morning, sometimes reporting the insight came to them in the form of a dream. Laboratory research has suggested there may be some truth to these claims. In general, sleep has been shown to play an important role in memory consolidation: stabilizing recently learned experiences into long-term memory, integrating those experiences with existing memories, and extracting new rules and generalizations. Such processes are not only critical for the adaptive functioning and updating of memory, but for facilitating creative insight and problem-solving.

In one laboratory study, participants were given RAT problems either before taking a nap or spending the same period awake. They were then given a second opportunity to solve the unsolved problems. Participants who took a nap involving REM sleep solved significantly more of the unsolved problems than participants who did not take a nap (Cai et al., 2009). Presumably, sleep allowed for the target solution words, which were exposed to participants as part of a seemingly unrelated task after the first problem-solving attempt, to become integrated with the RAT problems in memory, thus potentiating the participants' ability to solve the problems on their second attempt. Other research has shown that participants can gain insight into more direct ways of solving problems or make more generalized inferences about the relationships between different stimuli after a night of sleep than after the same period awake. Additionally, sleep has been shown to facilitate analogical transfer between problems. Beyond the updating and integrating mechanisms of memory consolidation, sleep may also facilitate creativity by causing a change in context that allows people to forget the information causing mental fixation.

Shared mental models mental models shared among members of a team working on a project

Strategies approaches or procedures that help people think about how to change the status of causes

Mental Models

Frank Lloyd Wright is widely considered one of the most creative architects of the 20th century. When one examines his work, however, a model of housing is evident in his early Prairie school work to his later work such as Fallingwater. It is a model which holds buildings should be embedded in their environment with limited embellishment. Einstein's general theory of relativity reflects a model of how energy and gravity operate at a macro, structural, level in our universe. Guilford's work on creative thought stresses divergent thinking—the production of alternative solutions.

All of the cases cited above point to a key conclusion: the work of eminent creative people seems bound together by an underlying theme or a way of viewing the domain in which they are working. Put differently, creative people seem to bring to their work a unique understanding of the phenomena of interest. Rouse and Morris (1986) argued that understanding of events in a certain performance domain is based on the mental model people use understand action, and action outcomes, in this domain.

This entry will examine how mental models contribute to creative performance, the production of original, high-quality, and elegant solutions, to complex, novel, and ill-defined, or poorly structured, problems. How shared mental models among team members contribute to the production of innovative new products and processes will also be considered. And finally, there will be a discussion of how people acquire and apply viable mental models in creative efforts. Before turning to these issues, however, let's examine what is meant by the term mental model.

Structure of Mental Models

Goldvarg and Johnson-Laird (2001) provided the most widely accepted definition of what is meant by the term mental models. They argued that in its simplest form, a mental model is the imposition of a cause-outcome linkage. In other words, the level at which a cause is operating is held to give rise to a certain outcome. Thus, a mental model common in the work domain holds that high job satisfaction gives rise to better job performance. Given this assumption, if you want my employees to perform better, you should take actions that will make them happier in their jobs. This observation is important because it underscores the point that mental models are inherently action oriented—causal assumptions specify potential actions to change the status of the cause. And, mental models are inherently adaptive. Mental models specify what outcomes a person should seek or avoid.

Of course, the description provided above of a simple mental model points to just how complex mental models may be. The first issue is what are the causes of concern? Yes, job satisfaction might cause job performance, but so might general intelligence. Second, what is the strength of the assumed relationship between each cause and the outcome of interest? Third, is the operation of a cause

contingent on the presence of certain conditions, a moderator, and what is the strength, or importance, of these moderating variables? Fourth, do causes operate directly on the outcomes of interest or is their influence indirect operating through another cause—a mediator? For example, does greater job satisfaction increase work motivation with work motivation resulting in better job performance? Fifth, what actions can be taken to increase a causal operative and how big will the effects of each action be? Sixth, how do the effects of actions on causes and outcomes unfold over time? Seventh, under what conditions will a given action prove effective, or ineffective, in changing the status of one or more causes, bearing in mind actions taken to increase one cause may decrease, or interfere, with the operation of other causes. Clearly, mental models can be very simple or highly complex.

Moreover, mental models can be accurate or inaccurate. Thus, in accounting for outcomes, a person may assume the correct causes are operating or use causes that are incorrect—causes that do not actually affect the outcomes of interest. In fact, prior studies examining the development of mental models of leadership over the course of peoples' careers found that mental models slowly, over time, become more accurate in that the causes articulated are those that actually are important.

Mental models are noteworthy for another reason. The causes and outcomes embedded in mental models provide a framework for integrating experience gained in working in a domain. Prior studies showed that plans for action are formulated through case-based, or experiential, knowledge. It has been argued that assumptions made about causes and outcomes are used to structure, or organize, experiential knowledge. Thus, not only are mental models built from experience working in a domain, mental models also provide a way of organizing and accessing this experience.

It should also be recognized that mental models are not emotionally neutral vehicles. People derive identity from the mental models they have constructed. Thus, model congruent and model incongruent events will induce affective, emotional, reactions. Moreover, people will act to "protect" their mental models, discounting events that might be taken to undermine their mental model. Indeed, it has been found when experts make errors, they often arise from routine application of a personally valued, expert, mental model.

Given their impact on plans and identity, many have sought to measure peoples' mental models under the assumption that differences in peoples' mental models will give rise to differences in performance. One technique used to appraise mental models is concept linkage, which includes indicating strong links between a given set of causes and/or causes and outcomes. Another technique used is cross association, or the associational linkage of certain words, or concepts, related to actions to be taken in a given domain. A third technique used is to ask people to draw, or illustrate, their model of a certain phenomenon. A fourth technique is to map concept linkages to the concept linkages used by recognized experts working in a field.

Regardless of the technique used to appraise differences in people's mental models, what is clear is that differences used by people to understand events arising in a given domain are strongly related to observed differences in peoples' performance. Thus, [Marcy and Mumford \(2010\)](#) showed that different content and structure of peoples' mental models for understanding university operations influenced their performance on a university simulation gaming exercise. Other work showed that more viable mental models are related to people's ability to cope with, perform well in, and address critical issues that arise in their jobs. In this regard, however, it is important to bear in mind the observations of [Rouse and Morris \(1986\)](#) with regard to the impact of mental models on performance—mental models appear to be most critical to performance when people are presented with novel, complex, high stakes events.

Mental Models and Creative Performance

Of course, creative problem solutions arise when people are presented with complex, novel, ill-defined, or poorly structured, problems. Thus, there is reason to suspect that peoples' mental models will also influence their performance on creative problem-solving tasks. In one of the earliest studies along these lines, [Finke et al. \(1992\)](#) asked undergraduate participants to draw aliens with the resulting drawings being appraised for originality. Notably, however, in drawing aliens, participants tended to preserve key features of biological life encountered on earth. Thus, most drawings preserved bilateral symmetry and eyes even though this requirement was not imposed—and alien life may not require bilateral symmetry or eyes.

Somewhat more direct evidence in this regard was provided by [Simper et al. \(2016\)](#). In this study, undergraduate participants were presented digital concept maps illustrating linkages among various concepts, or alternatively, participants were asked to write a story using a simple list of relevant concepts. Finding indicated that presentation of concept maps resulted in the production of more creative stories—especially with respect to judges' appraisals of story clarity.

In another study along those lines, [Malycha and Maier \(2017\)](#) asked participants, again undergraduates, to work on the product improvement task drawn from the Torrance tests, and the fluency, flexibility, and originality of the ideas generated was assessed. Complexity was manipulated by imposing (high complexity), or not imposing (low complexity), constraints. Participants were asked to illustrate concept linkages relevant to the problem, illustrate concept linkages using a template, or neither. They found that asking participants to illustrate their mental models resulted in the production of substantially more creative ideas ($d = 0.80$) than simple note taking—the control condition. Moreover, the strongest effects of asking participants to illustrate their mental models emerged when the conditions of task performance were more complex.

Clearly, specifically activating illustration of mental models, contributes to creative idea production. The questions that arise at this juncture, however, are 1) Does having a "better" mental model for understanding a task contribute to better performance in solving creative problems—not just simple idea generation? And, 2) What is the structure of viable mental models that result in the production of creative problem solutions? These issues were addressed in a study by [Mumford et al. \(2012\)](#).

Mumford and his colleagues examined peoples' ability to solve two, rather different, creative problems. One problem involved creating a plan for leading a new experimental secondary school. The other problem involved formulating an advertising campaign for a vintage footwear and apparel firm. Solutions to both problems, provided by some two hundred undergraduates in each study, were appraised by judges for quality, originality, and elegance. Prior to starting work on these problems, participants were asked to complete a self-paced instructional program, using a sports management illustration, where they were shown how to illustrate their mental models. Prior to starting work on the education task, or the advertising task, they received an email from a consulting firm on the education task, or from their putative supervisor on the advertising task, where a list of relevant concepts drawn from the literature was presented. Participants were then asked to illustrate their mental model for understanding the problem at hand using these concepts. Fig. 1 provides an illustration of one mental model formulated for the advertising study.

A panel of judges was asked to appraise objective and subjective features of the mental models provided. Objective features included number of critical causes, number of cause-outcome linkages, number of moderators/mediators, number of positive causes, number of negative causes, and number of reciprocal relationships. Subjective features included model coherence, novelty, logic, complexity, completeness. When these ratings were regressed on ratings of solution quality, originality, and elegance, multiple correlations in the low.30s were obtained. Thus, mental models appear to contribute to creative problem-solving. Moreover, it was found the most creative solutions were provided by people who used high importance, but not basic, concepts—who also took into account moderators and mediators of causal relationships. These mental models were, furthermore, coherent and logical, albeit not necessarily especially novel.

Mental models, of course, are an organizational structure, thus coherent organization of critical causes is more important than novelty. This observation, however, broaches a new question. How do people work with experiential cases embedded in these models to produce more original, high-quality, and novel problem solutions? One way this might occur is to change the structure of the mental model. Another way this might occur is to adapt the mental model to the demands of the performance setting at hand.

Hester et al. (2012) and Peterson et al. (2013) have examined the value of changing mental model structures. In both studies the education and advertising tasks were again presented, following instruction as to how to illustrate mental models in terms of structure, and the originality, quality, and elegance of problem solutions was assessed. In the Hester et al. (2012) study, participants were

Figure 1 Illustration of one mental model formulated for advertising study.

also asked to complete a set of self-paced training modules where they were presented with strategies for identifying causes: work with 1) critical causes, 2) causes that impact multiple outcomes, 3) causal interdependencies, and 4) causes that have negative effects. In the [Peterson et al. \(2013\)](#) study participants were presented with self-paced training modules where they were presented with strategies for identifying constraints: work with 1) resource constraints, 2) system capability constraints, 3) user skill constraints, and 4) goal constraints. It was found that training in both analysis of causes and analysis of constraints resulted in the acquisition of stronger mental models and the production of more creative problem solutions—solutions of higher quality, originality, and elegance, with such training proving especially valuable for people evidencing creative talent or potential.

Another set of studies by [Barrett et al. \(2013\)](#) and [Robledo et al. \(2012\)](#) examined the value of adapting extant mental models to the performance domain at hand. In the [Barrett et al. \(2013\)](#) study, people were asked to complete a set of self-paced instructional modules where they were taught to consider issues involved in developing and applying creative ideas: think about 1) How ideas will affect user groups, 2) The setting for idea implementation, 3) User group preparation and 4) Sustainability of the idea in context. In the [Robledo et al. \(2012\)](#) study, people were asked to complete a set of self-paced training modules where they were taught to think about potential errors arising in idea implementation: think about 1) error criticality, 2) error impact on stakeholders, 3) error controllability and 4) subsequent errors that might arise. In these studies, the instructions described above resulted in acquisition of stronger mental models and production of problem solutions of higher quality, originality, and elegance.

Taken as a whole, these findings indicate that people can acquire stronger mental models that lead to more creative problem solutions by manipulating model structure and/or adapting model content to the performance setting at hand. Of course, other techniques may also encourage the acquisition of stronger mental models in creative problem-solving efforts, and structural manipulation and adaptation might not be the only mechanisms of relevance. Nonetheless, these findings, along with those obtained in the studies discussed earlier, make a basic point—peoples' mental models appear to account for significant differences in their ability to solve problems calling for creative thought.

Collective Mental Models

Not only are mental models relevant to individual-level creative performance, they also appear critical to innovation. To turn creative ideas into viable innovative new products or services, multiple people, teams, and multiple stakeholder groups, must be drawn into the effort. If different people, or different stakeholder groups, have markedly different understandings of the nature and significance of the creative idea, or creative problem solution, performance and innovation will suffer. In fact, because innovative efforts often require chains of creative problem-solving efforts, for example, a new drug may require subsequent new ideas about how to manufacture the drug, the availability of a shared understanding of the idea at hand, and its implications, may be especially important.

Shared understandings in teams, or firms, are held to be based on team members evidencing a shared mental model. The existence of a shared mental model among team members is commonly identified by either appraising the similarity of content maps through a path finder analysis, or alternatively, appraising the amount of variance evident among team members in their appraisal of the importance of issues or concepts—note, low variation is held to provide evidence indicating the existence of a shared mental model.

A variety of studies have indicated that the availability of shared mental models contributes to team performance. For example, [DeChurch and Mesmer-Magnus \(2010\)](#) conducted a meta-analysis study of the availability of shared mental models and team performance. They found the availability of shared mental models resulted in better task execution (e.g., planning, goal setting, coordinating), greater team motivation (e.g., confidence, morale, identification), and, ultimately, better performance. In fact, the contribution of shared mental models to performance also appears to generalize to teams working on tasks calling for creative performance.

For example, [Santos et al. \(2015\)](#) studied the performance of one hundred and sixty teams who were asked to work on a complex managerial simulation exercise. Team members completed a survey describing their self-perceived creativity and creative self-efficacy near the end of work on this simulation exercise. Performance was assessed through “end of game share price”. The availability of shared mental models was established through agreement evidenced among team members with respect to task demands and team processes. Creativity was found to be strongly positively related to team performance. The availability of shared mental models, however, was found to be positively related to team creativity and reduction of conflicts among team members. Thus, the availability of shared mental models does appear to contribute to both creativity and performance within teams.

The availability of shared mental models among team members, however, is not simply a matter of team members' impressions of their own creativity. [Mumford et al. \(2001\)](#) asked teams to generate ideas for solving a set of creative problems, with the number of ideas generated serving as one measure of creativity. Teams were also asked to provide solutions to these problems where judges appraisals of solution originality and solution quality provided another measure of creativity. Shared mental models were induced, or not induced, by providing team members with training before they started work on the creative problem-solving task. They found that teams sharing a mental model not only produced more ideas relevant to the task, they also produced more creative problem solutions—solutions of higher quality and originality.

In addition to task-relevant training, a variety of other techniques might be used to induce shared mental models in creative teams. It can be argued that three key activities in addition to training, or cross-training in other job functions, contribute to team acquisition of shared mental models. First, leaders should actively, and clearly, articulate their personal mental model for

understanding the creative effort. Second, after action reviews of work accomplished should include analyses of performance, and team feedback, with respect to shared mental models. Third, ongoing communication among team members vis-à-vis the creative effort should be encouraged to spur the emergence of shared mental models.

Developing Mental Models

Our foregoing observations, of course, suggest that mental models, and shared mental models, can be developed. This statement, however, broaches another question: what techniques might have value for developing viable mental models and viable shared mental models as individuals and teams undertake creative efforts? In fact, four techniques: case analysis, goal analysis, forecasting, and active deep reflection, all appear to contribute to the acquisition of viable mental models.

Perhaps the most straightforward approach to developing peoples' mental models may be found in training, or educational, interventions intended to help people work with the two core elements of all mental models—causes and outcomes or goals. The value of training people to work with causes was demonstrated in a series of studies by [Marcy and Mumford \(2010\)](#). In the first study, undergraduates were asked to solve six creative problems drawn from business and education domains. Judges appraised the originality and quality of the resulting problem solutions. Prior to starting work on these problems, however, participants were asked to complete seven self-paced instructional modules where they were provided with more effective strategies for working with causes: work with 1) causes that have large effects, 2) causes that effect multiple outcomes, 3) causes that can be manipulated, 4) causes that can be controlled, 5) causes that operate together, 6) causes that operate synergistically and 7) causes that have direct effects. It was found that this training in causal analysis strategies contributed to the production of more creative problem solutions.

In the second study, participants were asked to work on an educational leadership simulation exercise. Again, participants were, or were not, asked to complete the seven training modules bearing on viable causal analysis strategies. In this study, however, it was found not only that causal analysis training resulted in better performance, it also resulted in the acquisition of stronger mental models for understanding the performance setting at hand. Thus, training causal analysis, apparently, contributes to the acquisition of stronger mental models and better performance on creative simulation exercises.

Less attention has been given to the analysis of outcomes or goals. However, at least one study, a study by [Strange and Mumford \(2005\)](#), points to the value of developing mental models by encouraging analysis of potential outcomes or goals. In this study, participants were asked to assume the role of principal of a new experimental secondary school and participants were presented with good, or poor, as well as successful, or unsuccessful, cases of describing prior educational interventions. They were instructed to analyze these cases with respect to causes, goals, both, or neither.

It was found that analyzing good cases with respect to causes and bad cases with respect to goals resulted in the most creative problem solutions. Thus, there is reason to suspect that goal analysis strategies might also contribute to the acquisition of stronger mental models. This study, however, is also a reminder that viable mental models may emerge as a function of the cases, or experiences, on which they are based. Thus, in developing stronger mental models, it may be desirable to provide people with viable case prototypes which serve to illustrate critical cause-outcome linkages.

The [Strange and Mumford \(2005\)](#) study, however, is noteworthy for another reason. In this study, a manipulation was made where people were asked, or were not asked, to reflect on their own personal experiences when considering these cases. It was found that deep self-reflection contributed to the production of more creative educational plans. Thus, it seems plausible to argue that ongoing reflection on experience, potentially including unusual experiences or new, broadening, experiences, might also contribute to the acquisition of stronger mental models and the production of more creative problem solutions.

In this regard, however, reflection need not always be tied to actual past experiences. Prior studies showed that more extensive forecasting of the potential outcomes of planned actions contribute to both the production of higher quality, more original, and more elegant solutions to creative problems as well as more effective execution of key creative thinking processes (e.g., idea generation, idea evaluation). What is of note here, however, is that extensive reflection on the nature, success, and potential outcomes of forecasted actions may also contribute to the acquisition of stronger mental models.

Conclusions

Clearly, a variety of techniques can be used to help people acquire the kind of mental models likely to contribute to creative thought. Although more research is needed on how mental models contribute to creative problem-solving, for example, how should mental models be structured, and how should they be appraised, the findings to date indicate that mental models may be a powerful force shaping the nature and success of peoples' creative thought. These findings point to a need for more work intended to help us learn how to develop viable mental models.

In fact, work along these lines could be especially important because mental models may either inhibit or facilitate creative thought. Remember, [Finke et al. \(1992\)](#) findings indicated that mental models inhibited creative thought. Other work indicated the formation of viable new mental models often provides the basis for eminent achievement—in fields such as science, advertising, and architecture. Given these complex effects of mental models on creative achievement, there is clearly a need to know more about the exact structure of mental models that makes creative thought possible. The authors hope this entry provides an impetus for further work along these lines.

Introduction

Developing the efficacy and drive to become an active contributor to creative thought and ventures can be a daunting task. Creativity is often viewed as an inherent trait afforded to only a few individuals. However, taking a social or developmental view of creativity in which individuals can develop an ability to be creative, we can consider the impact of contextual variables and key supporting relationships on the involvement in creative activities and subsequent creative achievement. An important relationship to consider here is the connection between a mentor and a mentee. Indeed, in areas as diverse as science and film, many exemplars of creative achievement benefited from relationships with mentors. James Watson, co-discoverer of DNA, learned from Max Delbruck, an eminent scientist and recipient of the Nobel prize in physiology or medicine. More recently, Steven Spielberg served as a mentor to fellow director J.J. Abrams. Through these illustrative examples we gather that mentoring often serves as a means of interpersonal learning that can support individual creative development.

Broadly, focusing on creativity, mentors provide support and developmental opportunities to their mentee that can encourage creative idea development and generation. Accordingly, this entry focuses on the social and developmental view of creativity by examining the relationship between mentorship and creativity. The chapter starts by outlining what is meant by mentorship and the roles mentors serve. Subsequently, by highlighting key studies in this area, the impact of mentoring actions on mentee creative learning and performance is reviewed. Finally, the steps required to promote mentorship for the unique benefit of creative performance are presented.

Mentoring

Defining Mentoring

To understand what is meant by mentoring, a few component parts need to be considered. The most prototypical representation of mentorship is the wise leader, parent, or educator imparting guidance and knowledge onto those below them (the follower, the child, or the student). However, to start, mentoring can be defined through both formal and informal relationships, such that the mentor-mentee connection exists through official or unofficial paths. Mentorship can occur formally as the mentee is assigned to a specific mentor to receive guided assistance and development. An example here is the connection between a manager and his or her team members. Alternatively, informal mentoring can occur as the mentee seeks support or the mentor provides unrequested guidance. This distinction is important as mentoring moves past the consideration of those in a formal role and instead focuses on the specific relationship development between a mentor and mentee. Thus, mentorship can be provided formally or informally through multiple individuals across different settings.

However, an added distinction that nuances understanding of mentorship is the difference between mentoring relationships and mentoring behaviors. To illustrate, consider the connection between two peers or colleagues with one passing along career advice to the other. In this case, the individual is conducting a mentorship behavior, but a mentor-mentee relationship may not be specified or established. The mentor behavior may be a claim to take on a mentorship role or develop a mentoring relationship in the future, but no established bond or connection has yet been formed. The mentor-mentee relationship requires, and is more clearly present, through the pairing of individuals or the long-term development of a mutual connection. As such, although any individual can conduct mentoring behaviors, an established formal or informal mentoring relationship is required to ensure a lasting and effective impact.

Three additional components add layers of nuance to an understanding of mentorship. First, mentorship requires two parties, the mentor and the mentee or protégé (used interchangeably throughout this chapter). Bearing in mind these two parties, mentorship can be broadened to consider both groups and individuals, which allows for attention on situations ranging from

a leader providing guidance to their team to an academic advisor individually connecting and supporting an advisee. As such, the study of mentorship can be broadly defined. Second is the role of both the mentor and protégé as active contributors. Mentorship is not a one-sided endeavor where the mentor is the primary contributor; both parties can play a pivotal part in developing and promoting mentorship. The mentor can seek out those in need of guidance or the mentee can find an individual who is willing to share his or her experience. Lastly, the guidance that the mentor provides or the mentee seeks can be for both professional and personal development. Thus, the mentor-mentee relationship can range in support from career-specific guidance to more intimate and interpersonal advice.

The distinctions established above serve to demonstrate the breadth and depth of mentoring. One could easily identify examples of mentoring across age groups, work and non-work settings, and for a variety of intentions and purposes. Multiple individuals can take on a mentor or protégé role. The definition of mentorship is a formal or informal relationship between two parties with the intent of professional or personal development.

What Do Mentors Do?

In applying this definition to promote the professional or personal development of an individual, scholars have debated the specific role mentors serve; yet, three main functions emerge as most commonly considered (Kram, 1988; Scandura, 1992). The first, psychosocial support, consists of the building of trust and intimacy between the mentor and mentee. For this function, mentors focus on behaviors that help enhance their mentee's self-efficacy and support their personal identity development, such as role modeling, friendship, counseling, and encouragement. The second function, career-related support, focuses on the mentee's vocational interests and development. Mentors, in this case, encourage mentee's pursuit of career-related goals, preparing them for hierarchical advancement through coaching and exposure to challenging and difficult assignments. The third function, role-based support, promotes mentees' development in their current position. Here mentors provide mentees with the guidance as to the appropriate behaviors required for their role and how to manage expectations properly. Across the functions of mentoring, learning is the common denominator, as the general purpose of mentoring is to teach and prepare the protégé to succeed in their field.

Before proceeding to a discussion of mentoring and creativity, it is important to note that not all mentoring relationships are the same. As such, a mentor-mentee connection is not required to satisfy all three functions specified above. It is possible for a mentee to have multiple mentors who each serve to provide a separate aspect of support. In addition, mentoring relationships are not as static as they have been portrayed here. In fact, mentorship can vary in its purpose, duration, and patterns of interaction. Thus, the established definition and functions should be used as a guide instead of a set of unwavering rules determining what is and is not mentorship.

Mentoring and Creativity

Does mentoring support the development of protégé creative ability, creative involvement, and creative performance? To answer these questions, a social and developmental view of creativity is required (Mathisen and Bronnick, 2009; Tierney and Farmer, 2002). An individual's creative identity and ability can be built and can progress over time through active engagement in activities or discussions with their mentor(s). This perspective moves away from the traditional image of creative ability and thought as a solitary and static concept toward a malleable and evolving interpretation. Supporting this idea, available evidence specifies the importance mentors hold on growing protégé creative performance and involvement. Generally speaking, studies on mentoring point to the critical role of mentoring in developing key outcomes such as mentee creative self-efficacy and creative performance.

Creativity is commonly defined as the generation of an idea that is both novel and serves a purpose (Amabile et al., 1996). However, in creativity research, the final idea is not the only component of interest. When discussing creativity, one can consider an individual's tendency or ability to be creative, an individual's efficacy or identity as a creative contributor, and an individual's final creative achievement or performance. Accordingly, mentoring can impact individual creativity development across all three of these areas.

The value mentors hold can be accessed through two distinct paths. The first path centers on the final creative performance of an individual. Here the mentor serves a direct role, as they help shape or mold the final creative idea or product by integrating their perspective or challenging the mentee to push further. In this case, the mentor might become personally involved in the idea generation, selection, and development process. Alternatively, the second path focuses on the mentee's involvement in creative ventures and their development of a creative identity. For this path, the mentor takes a more indirect role. In this case, the mentor may serve as a support system providing resources and guidance, or building the protégé's motivation to behave creatively. These paths demonstrate that the learning and growth provided by mentors can impact mentee creative performance directly or indirectly.

Further, each of the three functions of mentoring, psychosocial support, career-related support, and role-based support, have both direct and indirect paths by which mentoring behaviors influence protégé creativity. In providing role-based support, a mentor can serve as a role model to help mentees learn and determine appropriate actions and behaviors. In creativity specifically, role modeling can indirectly impact individual creativity by demonstrating the appropriate behaviors required for the creative process. For example, the mentor can demonstrate the actions needed to generate ideas, evaluate the utility of ideas, and indicate how to bring ideas to fruition. Here the mentor is not directly impacting the mentee's creative product or ideas, but instead representing

an appropriate path for the mentee to take. As such, the mentee is learning how to behave creatively and engage in creative idea generation. However, the mentor might also take a more direct path by demonstrating and helping craft a creative idea with their mentee. Further, career-related support, concentrating on career-advancement and navigation, can also take on a direct and indirect path to impact mentee creativity. Directly, the mentor can share knowledge or provide guidance to the mentee to develop their creative idea or move forward with a creative venture. Indirectly, the mentor can connect the mentee to individuals outside of their network to support the development of a creative venture or support and validate the mentee's career decision to engage in creativity. Finally, the mentor can provide psychological support by counseling or encouraging the mentee to be creative. Given that engaging in creativity can be an arduous endeavor, the mentor indirectly supports creativity by boosting the individual's creative identity and belief in their creative abilities.

Support for the direct impact of mentoring behaviors on creativity comes from recent work by [Cai et al. \(2018\)](#), in which an entrepreneurial leadership style was found to predict individual creativity. At a high level, entrepreneurial leadership is aimed at motivating and guiding followers toward creative opportunities and endeavors; however, at a behavioral level, it is similar to mentoring for creativity, specifically in the context of the manager-employee dynamic. Entrepreneurial leaders engage in mentoring behaviors such as motivating employees to engage in the creative process and building their confidence in their creative abilities (i.e., psychosocial support), as well as working directly with employees to generate ideas, consider alternative perspectives, and overcome challenges (i.e., role-based support). Thus, the ability of this leadership style to drive creative outcomes is an indicator of the potential for mentoring for creativity to do the same.

When [Form et al. \(2017\)](#) asked participants to think of a mentor who influenced their personal development, they discovered that more traditional components of mentoring (namely, providing psychological support, advancing domain-relevant skills, career-related support, and role modeling) were not directly related to creative performance. However, an interesting new component of mentoring, interpersonal tensions was significantly related to mentee creative achievement. Although these results should be taken with caution provided issues of generalizing from a single self-report sample, what is important to highlight here is that mentoring can impact creativity through a negative path (i.e., interpersonal tensions). The authors theorized that the interpersonal tensions participants reported with their mentor were a byproduct of added intellectual stimulation or critique received from the mentor. If a mentor is critical of a protégé's ideas and rigorously evaluates the value and potential utility of the idea, interpersonal tensions may emerge, but creative achievement will also be higher. The mentor is serving as a key agent in the development of more original and useful creative products.

Alternatively, as discussed before, there is also support for an indirect path from mentoring to creative achievement. For instance, [Bang and Reio \(2017\)](#), through a sample of working adults recognized the importance of developing an individual's creative self-efficacy. Creative self-efficacy refers to one's belief in their ability to generate creative outcomes, which plays a pivotal role in individual motivation toward and engagement in creative ventures. To develop creative self-efficacy the authors considered the benefits mentors can provide as coaches, feedback givers, role models, and overall support systems. In addition, in this study, the individual mentee's personal accomplishments (i.e., feelings of competence and successful achievement) were also considered as a source of creative self-efficacy. [Bang and Reio \(2017\)](#) found that both mentoring and personal accomplishments related to increased creative self-efficacy and the subsequent involvement in creative work. Thus, the mentor serves as an indirect impact on creative achievement by building and fostering the protégé's belief in their ability to produce creative outcomes.

Hinted at in the findings of the previous study is the mentee's individual qualities that draw in mentors and increase creative performance. Although some mentor-mentee relationships emerge naturally, there is evidence to indicate that high-achieving individuals seek out mentors earlier in their careers. For example, [Zuckerman \(1977\)](#) found that Nobel laureates tended to have eminent scientists as mentors and that those relationships were the outcome of an active, mutual search by young scientists and their future mentors. Further, [Mumford et al. \(2005\)](#), found that active pursuit of mentorship was a key difference between high- and low-achieving scientists. This finding indicates that it is important to consider individual mentee characteristics that might push them to seek a mentor, and thus boost their involvement in creative activities and build their creative identity.

[Liu et al. \(2015\)](#) identified two characteristics that are important for a mentee to consider to maximize their mentorship experience and increase creative achievement: learning goal orientation and impression management tactics. The first, learning goal orientation, is an aspect of one's personality that drives an active and consistent engagement in activities to develop and build one's abilities ([Dweck, 1986](#)). Individuals with a high learning goal orientation often seek challenging work assignments, pursue developmental opportunities, and enjoy difficult tasks. Second, impression management tactics are behaviors focused on developing desired social images to promote specific relationship benefits ([Wayne and Ferris, 1990](#)). Taken together, [Liu et al. \(2015\)](#) studied both of these characteristics in 917 formal mentor-mentee pairs. Their results indicated that having a high learning goal orientation leads to increased mentoring provided by the mentor and subsequent increases in protégé creativity. However, this relationship was stronger when the mentee engaged in mentor-focused or self-focused impression management tactics rather than job-focused tactics. Essentially, this study demonstrated that individuals who actively pursue learning opportunities such as mentorship are among those most likely to receive mentoring, in particular when they take steps to be perceived as competent and deserving of the mentor's investment. These results demonstrate that the mentee can also play an active role in increasing their creative performance.

Overall, the studies presented above examined the effect of mentoring on creativity. The key takeaway from these results is that the underlying processes by which mentorship impacts mentee development are learning and growth. Mentors can increase protégés' creativity by impacting their personal identity growth (increasing creative self-efficacy), personal skill development (role

modeling the creative process or providing developmental tasks), and personal idea or product improvement (critically evaluating and increasing originality and usefulness of mentee ideas).

Promoting Creativity Through Mentorship

Together, the findings outlined in this chapter provide a variety of practical considerations for both individuals and organizations seeking to foster creativity through mentorship. Special attention must be paid to ensure that mentoring relationships, whether formal or informal, are structured in such a way that protégés receive the psychosocial, career-related, and role-based support they need to increase their creative self-efficacy and attain creative achievement. The remainder of this entry focuses on a series of actions that individual mentors can take to more effectively support mentees, along with recommendations for organizations seeking to create mentoring programs for their employees or members.

Before any mentoring occurs, it is important to carefully match mentors and protégés. While it might be tempting to pair mentors and protégés based on demographic diversity, it is more beneficial to pair them on characteristics like similarity in attitudes, values, beliefs, and personality (Eby et al., 2013). When mentees are similar to their mentors in these areas, they tend to report higher levels of support from their mentor and higher overall relationship quality. However, although similarity is necessary to establish a relationship, too much similarity can also prevent the mentee from developing independently and establishing their own path (Simonton, 1984; Runco, 2014). Thus, in matching mentors and protégés, it is important to seek an optimal level of similarity. After a mentor pair is matched, a second key step is to establish a shared understanding of the purpose and rules of the mentoring relationship. The goal here is for both the mentor and mentee to communicate their respective goals for the relationship, preferred method of interaction, and expectations for accountability. These two steps will set the foundation for a successful mentoring relationship.

In some ways, mentoring for creativity is similar to any other form of mentoring. However, there are specific areas where mentors can add to the experience in ways that will promote their protégés' creative self-efficacy and overall creative performance. To foster creativity, mentors should:

- **Actively listen to mentees' ideas and experiences.** By establishing rapport and an environment of acceptance and open communication, mentors can inspire creativity and afford mentees the freedom to express creative ideas.
- **Help mentees shape an inspiring vision or goal for their career.** An important part of mentorship is to help mentees develop goals that are both practical and aspirational. Mentors can then assist on the path to achieve those goals by using their own knowledge and experiences to provide advice on navigating workplace processes, learning about the creative process, and acquiring job-specific skills. When practical, mentors can also provide accountability.
- **Be encouraging of mentees' creative endeavors.** One of the key outcomes of mentorship is an increase in mentees' creative self-efficacy. Mentors can help foster that self-efficacy by showing enthusiasm for ideas, providing constructive feedback and suggestions for improvement, and voicing confidence in mentees' abilities.
- **Challenge or critically (but constructively) evaluate mentees' ideas.** As mentees increase self-efficacy and creative ability, mentors can push the mentee to be more creative by challenging their ideas. This should be done constructively, such as pointing out concerns the mentee might not have considered or encouraging them to look at their idea from a different perspective. An important part of the creative process is evaluating ideas, and mentors can help mentees learn to more effectively do that.
- **Provide guidance when mentees face challenges in their creative process.** The aim here is not to solve mentees' challenges or generate creative ideas for them. Rather, mentors could discuss how a problem might be addressed, how they have handled such challenges in their own career, or provide introductions to those in their network who may have expertise or insight. Mentors should help mentees gain the ability to navigate such challenges on their own in the future.
- **Provide developmental opportunities to mentees to encourage their growth and creativity.** When possible, mentors can provide hands-on experiences in the creative process. This could include allowing mentees to participate in or observe a brainstorming session, connecting them to others in the mentor's network, or (if the mentor is a supervisor) giving them a stretch assignment that requires creative idea generation.

Each of the actions outlined above can be used in either formal or informal mentoring relationships. However, organizations seeking to implement formal mentoring programs can increase the effectiveness of mentoring in a few ways. First, when mentoring for creativity, early engagement in mentoring is one of the keys to success (Ligon et al., 2011; Mumford et al., 2005). As such, organizations should be sure to make mentoring available for recently hired employees and those who are newer to the field. Second, in some cases, it can be valuable to have multiple mentors with different perspectives and insights (Murphy and Kram, 2010). Organizations could structure programs so that mentees have a primary mentor who is responsible for more psychosocial and role-based support, along with a secondary mentor who is more senior in the organization and can provide longer-range, career-related support. Finally, as with any new program, organizations should provide training to those involved in the mentoring program – both mentors and mentees – to ensure they understand how to maximize the relationship and work together effectively.

These actions, undertaken by individual mentors or by organizations, can help individuals develop the drive and efficacy needed to be a successful contributor to creative thought and ventures. By providing psychosocial, career-related, and role-based support, mentors can boost mentees' creative identity and self-efficacy, and thus inspire increased creative achievement.

Summary and Conclusions

This review of the impact of mentoring on creativity leads to some thought provoking conclusions. The most important conclusion is that creative ability can be developed. Perhaps even more critical, research indicates that mentoring can support the development of creative ability. The impact of mentoring in creative thought and performance arises through the career-, psychological-, and role-based support mentors provide their mentee. Mentorship can provide the foundation for an individual to understand the creative process and build their creative self-efficacy to increase their creative performance. Thus, it is clear that high quality mentorship improves an individual's creative process and confidence in their ability to be creative. Mentors can challenge individual ideas and build upon them to develop a more creative final product. Given the complexity of generating, constructing, evaluating, and implementing an idea, mentorship appears to provide the reassurance or constructive criticism needed to ensure success. More centrally, high-quality mentorship appears to increase creative performance.

In addition, although mentors emerge as a key resource in creativity training and development, the influence of protégé actions and characteristics cannot be disregarded. Multiple aspects of the mentee's personality, beliefs, values, and behaviors can impact the quality and strength of the relationship between mentorship and protégé creative performance. Thus, when promoting mentorship it is important to consider both the aspects of the mentor-mentee relationship and the protégé's specific individual characteristics.

The multiple paths by which mentoring can impact individual creative performance are nuanced. However, by understanding how mentoring influences creative thought and performance it is possible to develop interventions and formal mentoring programs to encourage and promote creativity. Hopefully the steps presented here will lay the foundation for future work intended to nurture a greater impact of mentoring on protégé creative performance. Given the value in fostering individual creativity, any effort to develop creative ability is time well spent.

What Is Meta-Analysis?

Meta-analytic studies have become popular in educational and psychological research and creativity is no exception. As empirical evidence accumulates, scholarly understanding of creativity is expanding, although controversies are also emerging. Meta-analyses are useful to take stock of the existing empirical evidence reported by quantitative studies and resolve some of the controversies in the field. This entry briefly explores meta-analysis as a research methodology and then presents a summary of key findings from meta-analyses on creativity.

Definition, History, and Purposes

Gene Glass is the psychologist who coined the term, “meta-analysis.” He defined it as “the statistical analysis of a large collection of analysis results from individual studies for the purpose of integrating the findings” (Glass, 1976, p. 3). Meta-analysis has a relatively short history as a research methodology. The emergence of the term itself came from a synthetic process. Eysenck (1952) had questioned the benefits of psychotherapy for patients. In response, Smith and Glass (1977) disagreed and compiled 375 studies on the impact of psychotherapy showing its benefits. The same team also published another meta-analysis on the relationship between class size and academic achievement. They called this “meta-analysis,” but they were not the only ones experimenting with the new method. Around the same time, Smith and Glass were working on the impact of psychotherapy, Schmidt and Hunter (1977) were aggregating the validity evidence of employment tests, and Rosenthal and Rubin (1978) were synthesizing studies on interpersonal expectancy effects. The emergence of meta-analysis seems to be an example of a case of “multiples” in scientific discovery [see Matthew, Pygmalion, and Founder Effects].

Long before the term came into use, researchers from different fields such as statistics, physics, and social psychology aggregated different study findings to obtain an overall estimate (See Cooper and Hedges, 2009). Olkin (1990) cited R. J. C. Simpson and Karl Pearson’s work on fever inoculation as an early example. The first meta-analysis on creativity (i.e., Rose and Lin, 1984) was on the impact of creativity training. This subject turned out to be the most popular topic in meta-analysis over the years.

Meta-analyses combine studies on a given subject to obtain an overall estimate of relationship, difference, activity, or probability. It is no coincidence that this approach emerged from and is most often used in the field of psychology, because research results indicate sizable variability particularly in this field. While obtaining a general estimate over varied study outcomes is helpful, equally important and interesting is the attempt to explain this variability. This is the reason why the term, “moderator,” is of great importance in meta-analysis. Moderators are used to explain the variability in study outcomes that occur due to theoretical or methodological reasons. In practice, these moderators could be continuous or categorical variables that account for a variation in effect sizes. They typically serve as an independent variable. Glass et al. (1981) adapted specific

statistical procedures of the analysis of variance and multiple regression to meta-analysis. Moderators use it to explain the variability in effect sizes, which are used as the dependent variables. Therefore, although moderators help explain why effect sizes vary from one condition to another in the statistical sense, they serve as predictors or independent variables as part of the model-building process. This is the point where meta-analysis goes beyond a simple arithmetic mean calculation. The process of moderator identification and the coding process require a strong knowledge of research methodology and the literature. Therefore, two different meta-analyses may not report the exact same results, depending on the modeling, moderator categories and statistical analyses.

Strengths of Meta-Analyses

The popularity of meta-analyses goes beyond pragmatic reasons such as citation counts. Meta-analyses use study outcomes reported as their data, whereas most primary research in psychology, business and education use data from human subjects. The aggregation of conducted studies provides a big picture of research on a given subject. When a meta-analysis provides a clear pattern, this brings about more confidence in the research findings, which in turn, guides and facilitates future research and policy development. In this sense, meta-analyses help bring clarity to diverse research reports.

Compared to literature reviews, meta-analyses are more objective and less vulnerable to researcher bias as a result of a clear structure around the statistical procedures. Moreover, meta-analyses give researchers an opportunity to test hypotheses that may not easily be possible through primary research. In this sense, it is a distinct form of scholarship.

Criticism of Meta-Analyses

Meta-analyses have been criticized in different ways since the very beginning of the method itself (Eysenck, 1978), and issues have been discussed in later works (e.g., Ioannidis, 2016; Sharpe, 1997). Three major issues raised by these researchers are the probability of combining studies of different kinds, which invalidates outcomes, since this is analogous to combining “apples and oranges.” Second, meta-analyses outcomes are criticized for being biased because of the overrepresentation of published work over conducted, but unpublished, studies that are more likely to yield non-significant results. This is known as the “file-drawer effect” or “publication bias,” and different methods have been developed to identify or address this issue (Gurevitch et al., 2018). One recommended solution is to seek and include “hard-to-find” data, also known as “grey literature.” It consists almost all studies beyond journal articles, including unpublished works. Third, included studies may vary in terms of their “quality” while the inclusion of low-quality studies may reverse or change the findings. Therefore, researchers may prefer excluding studies with no control group or post-test, only designs that avoid the problem of “garbage in, garbage out.”

As a relatively new methodology, researchers suggested new approaches on some of these issues, and the software programs are often quick to adopt them into their packages. Acar et al. (2019) discussed each of these challenges in the context of creativity research. To give more structure to the meta-analyses and ensure quality standards, researchers and practitioners may turn to published guidelines such as the American Psychological Association’s Meta-Analysis Reporting Standards (MARS) and Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA).

With the development of these guidelines and the increasing number of empirical studies on the method itself, meta-analyses have become a major form of research. Creativity researchers have exploited this method extensively. Given that meta-analysis provides a general perspective on a particular research question, a review of all conducted meta-analyses provides a board perspective on the field of creativity. The next section does just that in order to take stock of creativity research based on empirical data.

A Thematic Analysis of the Published Meta-Analyses on Creativity

Meta-analytic studies are important for the field of creativity because they provide an empirical summary and overview of decades of research in the field. They not only provide insights on some controversies in the field but also reveal patterns that were not clearly visible in the primary sources. In this section are summarized published meta-analyses on creativity according to following thematic clusters: creativity training, intelligence, achievement and performance, psychopathology, motivation, neuroscience, personality, mood and problem-solving. Studies that did not fit any of these categories are presented in the “other” category.

Creativity Training

The impact of creativity training is the most popular subject of meta-analyses. The first meta-analysis on creativity (Rose and Lin, 1984) addressed this issue and, as of 2018, eleven others were identified on this subject. Rose and Lin (1984) examined the effect of long-term creativity training on creativity as measured by TTCT. They found that creativity training programs have a moderate impact on verbal creativity, especially on verbal originality. Similarly, Bertrand (2005) demonstrated that training moderately improves creativity and the increase was higher verbal creativity figural creative ability. Interestingly, the frequency of the length

of training did not have an impact on creativity. Later on, [Ma \(2006\)](#) focused on the effectiveness of creativity training and found a large effect of training programs on creativity. In terms of divergent thinking outcomes, originality had the highest effect size, whereas elaboration had the smallest. The kind of instruments measuring creativity, the experimental design and the duration of training did not significantly influence the creativity level.

[Scott et al. \(2004a\)](#) revealed that creativity training programs typically improve performance across criteria, settings and target populations. In another meta-analysis by the same team of researchers ([Scott et al., 2004b](#)), the type of training was a significant factor in enhancing creativity. Specifically, idea production and cognitive training were more effective than imagery training. [Huang \(2005\)](#) also demonstrated that all types of creativity training have a positive impact on creativity across age levels and beyond school settings. However, a creative problem-solving training program had the least training time and yet the highest effects on creativity scores. [Yasin and Yunus \(2014\)](#) identified seven approaches to improving student creativity in the field of technology and engineering, including creative problem Solving/problem solving, computer/technology applications, inventive problem solving or TRIZ, integration of creativity lectures, case studies and creativity counseling approach, group plays for pre-school students, operational mechanisms of group composition approach and a group interactive brainstorming approach. They found that all these approaches had a positive effect on the development of creativity across educational levels.

The field of creativity often disagrees on the “criterion problem,” and the findings of the meta-analysis reflect variations related to the selected criteria. For example, [Cohn \(1985\)](#) found that creativity training improves creativity, as measured by fluency and originality. However, creativity training is not as effective in fostering creative performance on tasks that are different than those used during the training. Interestingly, the same increase in creativity can be produced by motivation or warm-up activities rather than an extensive training program.

[Scope \(1998\)](#) investigated the effect of instruction on creativity in school-aged children. The positive effects of instruction on creativity were consistent across subjects and treatments. However, independent practice as one of the instructional variables had a positive effect on creativity scores whereas other techniques, such as time dedicated to instruction, structuring, reviewing, questioning and responding did not have an effect. This finding seems to draw a line between “good instruction” and “instruction that supports creativity,” and although the latter may lead to the former, the former does not guarantee the latter.

[Kwon et al. \(2016\)](#) found that invention programs had positive effects on K-12 students’ creativity in South Korea and [Tsai \(2013\)](#) found that creativity training is effective for adults. [Moga et al. \(2000\)](#) analyzed the association between studying the arts and creative thinking and found that the link depends on the research designs and measurements of creativity. Correlational studies indicate moderate relationships between two variables, and the connection becomes clearer when the figural form is used to assess creativity.

“Can creativity be taught?” This is the most popular question on creativity and the meta-analyses seem to bring some good insights to this question. The answer is clear that creativity training often works, and there are strategies and techniques to enhance it.

Intelligence

The link between creativity and intelligence intrigues many researchers in the field. Early tests of intelligence included divergent thinking tasks (See “Divergent Thinking”) that are typically used for the measurement of creative potential. Some validation studies of creativity tests, such as the Torrance Tests of Creative Thinking (TTCT), include intelligence as a potentially related predictor of creative achievement. For those who believe that creativity is a distinct construct, intelligence tests serve as a criterion to test the discriminant validity of creativity tests ([Wallach and Kogan, 1965](#)). There are many studies that test the validity of the threshold hypothesis that underlines the varying nature of the relationship between creativity and intelligence at different levels of IQ. This is why [Kim’s \(2005\)](#) meta-analysis is noteworthy, in that it shows that the correlation between creativity and IQ is $r = 0.17$, and not significant. Moderator analyses indicate that the correlation is lowest when Wallach’s and Kogan’s tests were used as a measure of creativity. This finding is important in terms of the discriminant validity of creativity tests and seems to question cognitive models that view creativity as a sub-component of intelligence. It also highlights the possibility that untimed and lenient testing conditions yield better discriminant validity as a result of less reliance on the speed of processing and test anxiety. Another significant moderator is aging, which enhances the relationship between creativity and intelligence. This finding may explain why people get more creative with aging as a result of a greater use of memory and executive processes involved creativity. The small correlation between IQ and DT is expected because the creative thinking process involves both convergent and divergent thinking (see “Convergent Thinking”).

In a subsequent meta-analysis, [Kim \(2008\)](#) found that the correlation between IQ and creative achievement is lower than the correlation between DT and creative achievement. Creativity tests were a superior predictor of creative achievement than tests of intelligence; thus, this meta-analysis provided support for the predictive validity of creativity tests.

Achievement and Performance

Some studies focused on factors that may impact people’s academic or creative achievement as well as creative performance. Information technology is one of such factors. [Pacauskas et al. \(2017\)](#) focused on how information systems affect the creative performance of individual users. Their findings indicate that task-related challenges may foster creativity if the user is in a state of flow. This makes perfect sense from the perspective of the research on the intrinsic motivation for creativity, which is another

area of meta-analytic study (see below). The user-friendliness of an information system diminishes the cognitive load during its use, which can positively influence that user's creative performance (See Flow).

Another factor is the network structure of any group in an organizational context. Porter et al. (2018) analyzed 62 different samples and found superior creative achievement with open networks, which are characterized by weak ties, allowing exposure to novelty and diversity of information, compared to closed networks characterized by mutual support for members. Connectedness with the entire network is associated with better creative outcomes, whereas having direct ties is related to creative process behaviors. People are likely to connect to their immediate contacts when they need to engage in creative behavior, but the success of the final outcome still relies on the connectedness within the entire network.

The creative performance of employees is also influenced by a number of factors. Xu et al. (2017) conducted a meta-analysis and found that creative employee performance has the strongest association ($r > 0.50$) with team performance, cognitive reevaluation, team identity, concentration, and performance-approach goal orientation, followed by ($0.30 < r < 0.50$) for performance-avoidance goal orientation, feedback consistency, mastery-approach goal orientation, charismatic leadership, internal motivation, motivation for identification, working motivation, inhibition of expression, psychological satisfaction and time pressure. They saw moderate to weak relationships ($r < 0.30$) with positive and negative moods, autonomous and control orientation, the need for autonomy, executive support and capability and relationship requirements.

Academic achievement is another area of research interest. Gajda et al. (2017) focused on the relationship between academic achievement and creativity; and their study revealed a positive correlation ($r = 0.22$). However, this relationship depended on the types of measures of creativity and academic achievement. Verbal creativity tests yielded higher relationships with standardized test scores as opposed to grade point average. Interestingly, verbal creativity is a significant moderator in Kim's meta-analysis, too. The correlation between creativity and intelligence is smaller with verbal creativity tests compared to other tests of creativity. It is clear that meta-analyses on creativity should include test stimuli (verbal vs. non-verbal) as a potential moderator.

Recently, Elaldi and Batdı (2015) conducted a small meta-analysis to examine the impact of creativity-based learning on academic achievement, which turned out to be significant (Hedge's $d = 0.73$ to 1.56). This study needed to be small largely because empirical evidence on the impact of creative pedagogy is lacking, in spite of a great amount of reflective, theoretical and anecdotal reports and studies.

Motivation

Motivation is another interesting field of controversy in the area of creativity where meta-analyses can bring clarity. The central issue of debate is the role of intrinsic and extrinsic motivation. Jesus et al. (2011) borrowed Mel Rhodes' 4 P's framework (person, process, press, and product). They found that creativity related to the person was significantly associated with intrinsic motivation. The type of sample moderates this relationship: the relationship between the two variables was higher among employees compared to students. After a decade, Jesus et al. (2013) further examined the relationships between the two variables based on creative outcomes or products. They identified a positive relationship between intrinsic motivation and creativity as related to the product. Contrary to their previous meta-analysis, this study did not reveal any significant differences between students and employees. However, the association between the two constructs was moderated by the type of research. Namely, intrinsic motivation was stronger in regard to creativity in the cross-sectional studies compared to those in the causal comparative designs.

Liu et al. (2016) showed that intrinsic motivation, creative self-efficacy, and prosocial motivation have a unique power in predicting employees' creativity at work. They also have different functions in relation to contextual and personal factors behind creativity. Intrinsic motivation and creative self-efficacy have a more positive influence on creativity in individualistic cultures compared to collectivist cultures.

As an external motivator, rewards can influence creativity. Byron and Khazanchi (2012) investigated the effect of rewards on creativity. Their meta-analysis concluded that creativity-contingent rewards are effective in fostering creative performance. When feedback is positive, contingent, and task-focused on performance, it had a stronger association with creative performance. On the other hand, performance-contingent or completion-contingent rewards seem to have a small, negative effect on creativity. Therefore, the type of reward determines its influence on creativity.

Mood

Many studies on the impact of mood were meta-analyzed by Baas et al. (2008). They found that a positive mood led to more creativity than mood-neutral controls, but there seem to be no significant differences between positive and negative moods. Further detailed analyses indicated that a positive mood is activating, leading to motivation and a focus on promotion, which are more influential on creativity, as compared to avoidance motivation and a prevention focus. Davis' (2009) meta-analysis also supported the notion that a positive mood fosters creativity. However, the pattern of effect sizes demonstrated a curvilinear relationship between affective intensity and creative performance. This analysis shows that there are no benefits of negative moods for creative performance. As an example of negative moods, Byron and Khazanchi (2011) found that anxiety was negatively associated with creative performance. Specifically, trait anxiety had more detrimental effects on creative performance than state anxiety.

Personality

Meta-analytic studies indicated that personality traits are associated with creativity. Based on the Five-Factor Model dimensions, the meta-analytic studies (Karwowski and Lebuda, 2016; Puryear et al., 2017; Zare and Flinchbaugh, 2018) reported strong positive predictors such as openness, extraversion, and conscientiousness with openness was the clearest factor. However, this association also depended on the type of creativity assessment. The effect sizes were stronger when domain-general measures were used rather than domain-specific measures. Similarly, Puryear et al. (2017) found a stronger relationship with production (e.g., product development) rather than ideation (e.g., divergent thinking) and with self-reported measures compared to other-rated measures. Zare and Flinchbaugh (2018) also compared self-report ratings to other-report ratings that demonstrated a stronger relationship between openness and creativity; on the other hand, the source of the rating had no effect on the relationship between voice and the Big Five personality traits.

Feist (1998) found that creative people in the arts and sciences share personality profiles, including openness, conscientiousness, self-acceptance, hostility and impulsivity, regardless of the type of measure or taxonomy used to assess personality and creativity. These findings have implications for the mad-genius hypothesis, which are discussed later in the section on, “psychopathology.”

Neuroscience

Recently, meta-analytic studies have emerged in neuroscientific investigation of creativity with the help of brain imaging technology. Mihov et al. (2010) examined the brain’s hemispheric specialization and creativity, and found that the right hemisphere is dominant in creative thinking. A global thinking style, a context-dependent thinking style, and figural processes are significantly related to right hemisphere dominance. Using functional imaging studies, Gonen-Yaacovi et al. (2013) reached a different conclusion. They located some predominantly left-hemispheric regions (i.e., the caudal lateral prefrontal cortex, the medial and lateral rostral prefrontal cortex, and the inferior parietal and posterior temporal cortices) that share different creativity tasks. There was task-specific regional activation. For example, tasks involving the combination of remote information activate more of the anterior areas of the lateral prefrontal cortex than those involving unusual generation tasks. In general, some frontal and parieto-temporal regions seem to support cognitive processes during various creativity tasks in addition to others (See Neuroscience:fMRI).

Pidgeon et al. (2016) synthesized functional neuroimaging studies of visual creativity. Visual creativity produces significant activation in the thalamus, the left fusiform gyrus, and right middle and inferior frontal gyri. They also found a lower alpha during visual creativity. These conflicting findings are sometimes observed in meta-analytic studies, and a number of factors such as the scope of the study, research design, or analytic method may contribute to the inconsistency.

Psychopathology

Some meta-analysis studies resolve the controversy on creativity and the mental illness link, also known as the “mad-genius hypothesis.” Benham (2004) emphasized that the link between the two variables depends on how the psychopathology is measured. Studies using interviews, psycho-biographies and eminently creative subjects reported stronger relationships than objective measures with non-eminant participants. Therefore, the study design remarkably influenced the results. Paek et al. (2016) analyzed the relationship between common psychopathologies and everyday creativity. This analysis indicates that the link is weak overall and stronger among those with a high intelligence. This finding explains why the mad-genius hypothesis is more often found among eminently creative individuals rather than laypeople. It is possible that people with a high IQ and psychopathology may be more successful in channeling their potential into creative pursuits than others with a lower IQ.

Taylor (2017) found that the relationship between creativity and mood disorder depends on the research design. Creative people show a higher instance of mood disorder compared to noncreative people, but the creativity of people with a mood disorder and healthy people does not differ. The association is significantly higher in individuals with cyclothymic and unspecified bipolar disorders than in a unipolar disorder. Creativity measurements of accomplishment and behavior indicate significant relationships with a mood disorder (See Bipolar Mood Disorders).

As Benham (2004) suggested, the link between creativity and psychopathology varies across different levels and forms of psychopathology, which is why some researchers have used a more focused approach. Acar and Runco (2012), for example, examined the association of creativity with psychoticism and found that the overall relationship was small ($r = 0.16$). Another meta-analysis by Acar and Sen (2013) revealed even further differences within schizotypy. The association between creativity and schizotypy is not uniform, and the type of schizotypy has a significant impact on creativity. Namely, Positive-Impulsive and unspecified schizotypy are positively related to creativity ($r = 0.14$), whereas Negative-Disorganized schizotypy has a negative relationship ($r = -0.09$). A recent meta-analysis by Acar et al. (2018) shows that the relationship between creativity and schizophrenia is negative ($r = -0.32$), and the nature of the relationship is influenced by the way creativity is measured, the severity of the schizophrenia, the content of the creativity test and the patient type. The negative relationship is stronger when creativity is assessed with a semantic-category or verbal-letter fluency tasks rather than divergent thinking or associational measures among people with chronic schizophrenia as opposed to acute states and early onset levels. Studies with inpatients show significantly higher negative associations than outpatients. Acar et al. (2018) concluded that the relation between creativity psychoticism continua seems to demonstrate an inverted U shape, where sub-clinical levels may help creativity, while a strong or full demonstration of the symptoms diminishes it.

Byron et al. (2010) examined the relationships between stressors and creativity. Their study results suggested that the association depends on the level and type of stress induced. Low-level stress is associated with higher creative performance, whereas high levels decreased it. Uncontrollable stress decreases creative performance whereas the social-evaluative form did not. Also, low evaluative contexts improved creativity over control conditions, whereas highly evaluative contexts had a negative impact on creativity. Putting these together, there seems to be a curvilinear relationship between stress and creativity. This is the conclusion of studies conducted by Acar on the psychoticism-schizotypy-schizophrenia spectrum (See Schizotypy).

Problem-Solving

Creativity is a natural aspect of problem-solving. Ma (2009) conducted a comprehensive meta-analysis of all the variables associated with creativity and found that the strongest association with creativity is obtained from problem-solving tasks and verbal tests compared to emotional and nonverbal tests. Specifically, problem definition and knowledge retrieval are strong correlates.

In another meta-analysis by Abdulla et al. (2018), problem finding and creativity were significantly correlated. The relation is moderated by the various components of divergent thinking, the problem-finding domain and the participant's age. Specifically, the mean effect size was higher in fluency and on originality scores than on flexibility and composite scores; it is highest in the domain of writing and lowest in social studies and humanities. The highest was seen in grades 1 thru 6 and lowest in grades 7 through 12.

Others

Other published meta-analysis did not fit the above categories and hence are summarized here. Hunter et al. (2007) focused on *social and contextual influences* on creativity and found that situational factors such as support and autonomy are strongly related to creative performance, especially during challenging conditions such as high competition.

Lebuda et al. (2016) synthesized the relationship between *mindfulness* and creativity. Mindfulness has been found to be significantly related to creativity, but the relationship is weak ($r = 0.22$). The type of mindfulness moderates the associations between the two constructs. The open-monitoring aspect of mindfulness has a higher correlation than the awareness aspect of it.

Gender differences in creativity is another area of interest in the literature. Thompson (2016) showed that females show slightly higher creativity than males. The creativity construct and the type of creativity test moderate the relationship between creativity and gender. Differences are larger in DT tasks than others and in creative achievement rather than ability.

Said-Metwaly et al. (2018) examined the factor structure of the *Figural Torrance Tests of Creative Thinking* (Figural TTCT) by testing four factor models previously presented in the literature. Their results suggest that a two-factor structure model fits the data best. Fluency and originality subscales come under the "innovative" factor; elaboration, the abstractness of titles and resistance to premature closure subscales, is loaded under the "adaptive" factor.

Haase et al. (2018) investigated the relations between creative *self-efficacy* and creativity measures. Their study revealed a medium effect size correlation between two constructs ($r = 0.39$). Self-rated measurements have higher relationships with self-efficacy than with divergent thinking. The personal aspect of creativity seems to be most strongly related to self-efficacy, compared to the creative product and the creative process.

Conclusion

Creativity research is growing fast, as have meta-analytic studies on creativity. Some topics often revisited are the impact of creativity, the mad-genius hypothesis, and the role of personality, motivation and mood. There are two major reasons for this. First, there is more controversy surrounding these topics and meta-analyses are useful to bringing some clarity. Meta-analyses have reported linear effects such as a positive relationship between creativity and intelligence, openness, extraversion, intrinsic motivation and positive effects, as well some non-linear effects such as psychopathology. Second, a meta-analysis cannot be done when there are not a sufficient number of quantitative studies. That said, more meta-analyses should be expected in the future as new areas are explored by researchers.

Definition: Then and Now

Although this entry regards metacognition, due to the strong theoretical and empirical tie between metacognition and motivation, a limited number of reviews on motivation is included in places to provide a better sense of the context of this entry. As learner engagement in metacognitive activity is largely hinged on learner motivation to participate in such activity, this section begins with self-regulation as the construct is related to both metacognition and motivation.

Metacognition is a component of manifested self-regulated learning postulated within the social-cognitive theoretical framework (Zimmerman, 2000). Self-regulated learning is derived from earlier work by Flavell (1979). Flavell defined metacognition in areas including metacognitive knowledge, metacognitive experience, activation of strategies, and goals. Metacognition was then separated into 'knowledge about cognition' and 'regulation of cognition.' Metacognitive knowledge indicates awareness of one's own declarative, procedural, and conditional knowledge and strategies. Metacognitive regulation involves planning, monitoring, evaluating cognitive operations, and selecting and using cognitive strategies effectively by combining, discarding, and coordinating various strategies.

From this distinction, 'regulation' of cognition expanded into contemporary self-regulation that includes motivation in the model. This addition signifies the close relation between metacognitive and motivational aspects of self-regulation in the learning and problem solving process. In this formulation, self-regulated learners are described as highly motivated as they view tasks as useful, important, or interesting, are self-efficacious, and monitor and regulate their efforts and perseverance during tasks; further, self-regulated learners are aware of their own knowledge, strategies, and thinking process and regulate the use of metacognitive strategies during tasks.

While acknowledging metacognitive processes as fundamentally important human cognition for creativity and problem solving, Sternberg's (2001) description of 'creativity as a decision' supports the notion that motivation is a driving force for creativity and that metacognition helps maneuver creative process. As such, in studying the relation between metacognition and creativity, including motivation as a variable, along with other related variables, will help better understand the nature of the relation between metacognition and creativity. Construct validation studies for self-regulation and its subcomponents, metacognition and motivation, have provided support to its structural validity on both state and trait constructs.

Diverse definitions and measures have been used in studies of metacognition as well as creativity, posing challenges in drawing conclusions and finding meanings about the relation of metacognition to creativity. The frequently quoted general definitions of metacognition (e.g., thinking about one's own thinking or cognition about cognition) does not convey what particular researchers might mean about metacognition, and this constitutes a cautionary note for research consumers, as the disparate uses of the term metacognition continue to the present day.

Relations of Metacognition With Learning, Motivation, Mind Wandering, and Creativity

To provide context for discussing the relation of metacognition with creativity, relations of metacognition with learning, motivation, and mind wandering are reviewed first, followed by its relation with creativity. Although learning, motivation, mind

wandering, and creativity are interrelated among each other and with metacognition, they are separately addressed to place an emphasis on each.

Metacognition and Learning

Metacognitive abilities have been noted as positively related to learning, as effective uses of metacognitive strategies have been documented as having a significant role in academic achievement. However, a nonsignificant relation has also been reported in several studies. This relation varies across grade levels, showing the effects of learning environment and other related variables that come with school aged children on metacognitive skill uses. For example, the metacognition-learning relation in a study demonstrated that the relation was significant in middle school students, but not in high school students.

Metacognition plays a central role when solving open-ended problems. Although experts may possess superior metacognitive skills than do novices, experts do not necessarily make more metacognitive statements than do novices. This phenomenon may occur because experts' metacognitive skills have been proceduralized. The automatic processing or proceduralization of expert skills should not be confounded with cognitive processing of learners who lack explicit awareness of what they are engaged in. An individual who can solve complex problems but is unable to explain how he or she found a solution could be a person who may or may not be highly metacognitive.

Metacognition and Motivation

In self-regulated learning models, metacognitive regulation processes are pervasive. Equally pervasive are motivation sources (e.g., self-efficacy, persistency, autonomy, value, interest) as metacognitive regulation applied by the learner is largely dependent on whether they are motivated to regulate their cognitive processes. Similar to metacognition, motivation is a complex psychological phenomenon with no one principal overarching theory or definition. In the past few decades, theories such as social-cognitive theory, self-determination theory, and expectancy-value theory have been advanced, some of which offered variables that have demonstrated close relations with metacognition. Students' motivation level and metacognitive strategy use have been shown to be positively related in various studies.

The essential role of motivation in the creative process has been emphasized by a number of researchers. (See Motivation) [Hong et al. \(2009\)](#) distinguished intrinsic motivation into two different manifested motivations—favoring and enjoying 'challenging work' versus 'creative work,' with the distinction supported by factor analysis. When the two types of intrinsic motivation were included in a path model for testing their effects on creative performance, only intrinsic motivation for creative work demonstrated a positive relation with creative performance ([Hong et al., 2016](#)). Types of thinkers (analytical vs. creative thinkers) might have been a factor in this finding. Individuals motivated by challenging and difficult work tend not to engage themselves in creative thinking that allows them to produce divergent and original solutions, possibly because they are more analytical than creative thinkers. This distinction was also demonstrated in a study that examined teachers' classroom practice; teachers with high intrinsic motivation for creative work reported practicing more creativity-fostering instructions as compared to teachers with high intrinsic motivation for challenging work ([Hong et al., 2009](#)). Different patterns of alpha activities were shown in the brain for convergent versus divergent types of responses, supporting different brain processing for creativity-related versus non-creativity-related performance. Thinking styles might have impacts on the use of metacognitive abilities and motivational attention, an area which requires more research to unravel the relations among these variables.

Metacognition and Mind Wandering

In recent years 'mind wandering' surfaced as a construct for investigations in its relation to metacognition. [Smallwood and Schooler \(2015\)](#) described mind wandering as a dynamic and fluid conscious experience from a current task to unrelated thoughts and feelings, suggesting the importance of its association with metacognition for determining functional outcomes of mind wandering. In pursuit of how metacognitive awareness and the control of mind wandering occurs, researchers reasoned from various brain studies indicating that metacognitive monitoring process might help catch and regulate one's mind wandering and may minimize the downsides of mind wandering while maintaining its productive aspects. What has not been discussed is if mind wandering would occur for those who built a habit of metacognitive processing, controlling their learning or creative process, and if there would be any negative effects with applying metacognition at all times during learning and creative process.

Mind wandering seems to increase metacognitive awareness when performing a task. [Allen et al. \(2013\)](#), in examining the default mode network (DMN), a large-scale network focused on the medial prefrontal cortex and the posterior cingulate cortex, and the network that supports decontextualized cognition, found greater metacognitive awareness of the errors committed during the task, suggesting that mind wandering and self-monitoring are intertwined. Whereas turning attention outward with high working memory capacity facilitates analytical problem solving, creative and original solutions can be challenged or weakened with excessive outwardly focused attention. Relatedly, inwardly focused attention for examining one's thoughts facilitates new and creative solutions to problems ([Wiley and Jarosz, 2012](#)) (see Breadth of Attention).

Metacognition and Creativity

Metacognition has long been associated with creativity (Feldhusen, 1995), suggesting that creative-thinking skills operate in concert with self-monitoring and self-evaluation to sustain creative thinking. Whereas some empirical research supported this relation, this view has not been consistently supported in other studies. Some of the research studies that demonstrated positive effects of metacognition on creativity are presented below followed by those indicating no effects.

Metacognition and Creativity: Positive Relations

Metacognitive process and its positive association with creative problem solving or creating novel products have been reported. The role of expertise in the relation of metacognition with creativity has been discussed in terms of self-regulatory process (Steele et al., 2017). Steele et al. contended that exploratory regulatory processes are critical during the initial stage of creative performance, especially at the problem finding stage, by reasoning that expertise facilitates creativity as experts have well organized deep domain relevant knowledge. That expert's knowledge of subjects and context and their experience play an important role in the activation of metacognitive process was supported in research. For example, artists, as compared to non-artists, engaged in more metacognitive activities during the creative process, although there was no difference in metacognitive evaluation between artists and non-artists as participants in both groups self-evaluated their work throughout.

It is worth noting that the type of school moderated the effect of metacognition on creative problem solving (Preiss et al., 2016), with the significant effects of metacognition on creativity showing in university students but not in vocational college students. Perhaps university students were more equipped with knowledge relevant to the research topics and tasks than were those from vocational college. Additional investigations on age and the type and level of education of research participants and other qualifying variables will further clarify the dynamics of the relation between metacognition and creativity.

Stressing that measures of creative potential (ideation) should be distinct from those of creative products, Puryear (2015) tested the role of metacognition as a moderator for the relation between creative ideation and creative production. In comparing the major components of metacognition (knowledge of cognition and regulation of cognition), Puryear found knowledge of cognition showing a stronger moderating effect than regulation of cognition, to which Flavell's (1979) emphasis on the knowledge component of metacognition was referred. Within the knowledge component, declarative knowledge (knowledge of self, resources, and ability) was the strongest moderator.

Metacognition and Creativity: No Relations

Effects of metacognitive skill use on creativity have not been consistent. Nonsignificant effects of metacognitive skills have been shown especially when other relevant variables are included in research studies. In Preiss et al. research (2016) regarding the effects of metacognition and mind wandering on creativity, other variables such as fluid intelligence, reading difficulties, and type of school were included to control their effects on the relation of metacognition and mind wandering to creativity. Metacognition did not significantly predict creative performance measured by creative solutions generated in divergent thinking and problem solving. Instead, mind wandering predicted both creativity outcomes. Some of these results were explained by Fox and Christoff's (2014) proposition that separates the creative process into 'generative' and 'evaluative' process. Fox and Christoff postulated that creative generation is largely based on spontaneous thought process, whereas creative evaluation involves metacognitive engagement. Steele et al. (2017) also suggested similarly that metacognitive activities might occur more often during optimizing creative performance. That is, when participants are evaluating creative solutions, rather than when generating them, metacognitive activities occur more frequently, a theory that still requires more validation.

In a similar vein, Hong et al. (2016) found deliberate metacognitive processes reported by research participants did not have an effect on creative performance. The results of structural equation modeling demonstrated that when the effects of trait metacognition and correlations among trait motivation and trait metacognition were controlled, state metacognitive activities did not show effects on creative performance. In addition, creativity measures may explain this finding further, as creative activities in this study required generative process that may not necessarily recruit metacognitive skills in the process.

In another study either of the two indicators of metacognition (knowledge of cognition and regulation of cognition) did not predict mathematical creative ability when the effects of openness to experience, intrinsic motivation, and one of the two indicators of metacognitive tendency in turn were partialled out. Variables that predicted mathematical creativity were intrinsic motivation and openness to experience, demonstrating the impacts of motivation and personality on creative performance beyond metacognition. These studies point to the importance of including relevant related variables and understanding of the type of creativity measures when examining the relation of metacognition with creative performance.

Summary

Fox and Christoff's (2014) descriptions of mind wandering (undirected and spontaneous thought processes) and metacognition (conscious, intentional regulation of thought processes) seem to suggest that the two constructs are opposite in their meaning and functions. As they describe how the first appearance of distinct differences becomes a dynamic interplay between the two seemingly different constructs, it challenges the common and simplistic view that metacognition and creativity are linked. Fox and

Christoff not only made the distinction between creative generation and creative evaluation (called also metacognitive evaluation) but suggested that a temporal separation between the two (i.e., sequential engagement of creative generation and creative evaluation) increases creativity of the outcomes. Further, deducing from the analysis of neural correlates of creative evaluation and creative generation, they contended that metacognitive evaluation may facilitate future creative generation efforts to produce novel and useful ideas identified while engaged in previous metacognitive evaluation phases.

Depending on the type of creativity of interest, metacognition may be best employed at different stages of the creative process (Steele et al., 2017). For example, for incremental or expected creativity, metacognitive activity should be high at the outset. On the contrary, when radical or highly novel creativity is sought, metacognition should be delayed at the outset, as radical creativity is usually linked to the combining of disparate areas of knowledge.

Essential to remind us—the researcher (knowledge makers) and the reader (knowledge consumers)—is that the direction and size of the relation may change depending on what other related variables are included in each research and how they are presented and measured in designing research, among others. Whether creative endeavors turn out as success or failure depends on a complex system of human cognition, motivation, and other variables such as personality and environmental factors. Overall, as the empirical relation between metacognition and creativity has not been strongly established, continued research is needed.

Metacognitive Instruction

Provided in this section are discussions of (a) explicit instructions and programs for teaching metacognition and (b) effects of metacognitive instructions on creativity.

Explicit Instructions and Programs for Teaching Metacognition

Trainability of metacognitive skills in relation to the development of creative thinking abilities has been discussed. For students to develop metacognitive abilities, students need to be given opportunities to learn and practice the skills. Teachers of young children to college students have an important role in providing learning environments that help students accumulate metacognitive knowledge and activate metacognitive regulation. To be able to create such climates, teachers need to be equipped with deep understanding of what metacognition entails. Increasing teachers' own metacognitive knowledge and developing metacognitive skills through numerous metacognitive experiences are essential steps to achieve the status where they can help students learn to be metacognitive in learning and creative process. Having knowledge of cognitive, metacognitive, and motivational strategies as well as experiences in regulating knowledge and strategy applications would be valuable in preparation for teaching their own students especially for solving complex and ill-structured problems and for being creative in such problem solving endeavors.

Intervention Programs: The Need for Encouraging Learning Environment

Beyond increasing knowledge of strategies, learners need to engage in the regulating process, planning, monitoring, and evaluating their own learning and problem solving process, and receiving feedback that allow for making corrections and adjustments. Explicit instructions and learning opportunities help learners reflect on the metacognitive knowledge they have gained and practice metacognitive skills they have learned, and gradually develop their own template or model that they can apply in various situations. Important in this process is that this type of learning may not occur in the absence of formal and informal teaching and training. A few examples of intervention programs are provided below.

Hu et al. (2013) provided students with opportunities to practice monitoring their own thinking in an intervention program for increasing scientific creativity. The program makes the teaching of metacognitive skills explicit through an organized procedure in which the teacher initially makes metacognitive strategies explicit and helps learners internalize the strategies with a goal to establish the strategies eventually become part of the learners' habitual mode of thinking. In this intervention each learning activity comes with a chance for students to summarize and reflect on their own thinking strategies, problem finding and solving methods, and on what was learned from their learning activities, with the intention that students will apply and transfer what they learned to other domains.

A supplemental course was used for teaching creative thinking strategies within a metacognitive framework (Hargrove and Nietfeld, 2015). Metacognitive skill development was fostered each week by integrating a new creative thinking strategy with metacognitive activities. Although this type of course at the university level may not be easy to implement because of limitations including scheduling and coordinating courses, it is feasible as long as creative and dedicated instructors are willing to make it happen. Existing courses can serve as good environments for teaching and learning and experiencing metacognitive skill use. From students of a very young age to adult learners, modeling metacognitive behavior can be a useful strategy. Teachers can think-aloud their own metacognitive process during problem solving by creating teachable moments where certain strategies can be used for monitoring and evaluating processes. The modeling must be followed up with an abundance of practice opportunities for learners to plan, solve, monitor, and evaluate, and repeat as needed with diverse problem situations over time.

Scaffolding is another way to help students learn metacognitive skills. Utilized in a program that used prompts for college freshmen's project-based community service learning, participating students were told to find innovative solutions to the problems they identified on site. In the process, students learned to use metacognitive strategies as well as creative problem solving strategies.

Students' learning of strategies was facilitated with a designed intervention, mainly utilizing email question-prompts that guided students to the end of projects. Likewise, instructors can help students enhance self-monitoring and self-facilitation by stating expectations that prompts and promote learner responsibility. Based on the benefits of active learning grounded in constructivist perspectives with a postulation that learners are in control of their own learning and are active processors of content, scaffolding built with the assumption of learner responsibility and management for their own learning process will likely help them develop metacognitive abilities and improve learning experience and performance.

Effects of Metacognitive Instructions on Creativity

Numerous articles, some theoretical along with a small number of empirical studies, underlined the importance of metacognition in learning and creativity activities, albeit not all research studies back the claim. Although creating learning environments to help students develop explicit metacognitive schema ready to be utilized for metacognitive practices has some support in literature, it is prudent to remember that such an endeavor building an instructional system requires the scrutiny of further research. The following includes research that has examined whether explicit instruction is effective in increasing creative performance.

Based on the understanding that frontal lobes maturation continues into early adulthood and the maturation is not yet consolidated in undergraduate students, [Reyes-Meza et al. \(2015\)](#) examined whether changes might occur in brain regions when students participate in activities that require them to use executive functions to promote their maturation. In an applied creativity course, students were asked to develop innovative proposals and present original solutions to problems by applying creativity concepts and techniques to significantly transform their environment. After the course work, changes to the anterior prefrontal area (PFAC) associated with an increment on executive functions were observed in some students. The changes regarded metacognitive judgment, metacognitive monitoring, and metacognitive control (the ability to develop a memory strategy). These changes were attributed to activities during the course that integrated exercises to increase the competence of autonomy and promoted self-evaluation of their own abilities at setting tasks to reach goals, thus generating functional modifications on the PFAC.

How explicit instructions can make a difference in creativity has also been studied by brain cerebral blood flow (CBF) examination. Whereas fluency and flexibility were strongly correlated with CBF in the left inferior frontal gyrus, originality was correlated with CBF in the left superior temporal gyrus and cerebellar tonsil, indicating that when the responders set their goals based on the test instruction, their processes of creative performance tapped different neural networks to meet the demand of the instruction.

Hargrove and his colleague conducted research studies to examine the effect of deliberate metacognitive instruction on metacognitive development and on creativity in design education. [Hargrove and Nietfeld \(2015\)](#) posited that through metacognitive reflection, designers progressively build more formal theories that allows for intentional attempts to apply their creative thinking skills to design applications. Their research approach included encouraging participants, undergraduate students in a design course, over a 16-week period, to develop metacognitive skills to generate creative solutions to design-based problems. A new creative-thinking strategy was introduced each week with a specific purpose to help student develop metacognitive ability. The research results supported their postulations with the treatment group showing metacognitive awareness scores increasing over a course while the comparison group stayed stable. Students in the treatment condition also showed higher creativity scores compared to their counterparts in the comparison group (see Teaching Creativity).

Research on metacognition and creativity has been steadily growing in various fields, primarily investigating the relation of metacognitive ability with creative process and outcomes and building instructional models for application of metacognition in specific disciplines. The fields that have shown interest and made progress in understanding and applying metacognition in teaching, learning, and product outcomes include mathematics, science, secondary language, technology, engineering, information systems and management, nursing, various areas of design education, and military personnel training. Cultural metacognition—cultural consciousness and awareness during social interaction—has been a topic of interest in situations where multicultural team work is required.

Conclusion

Although a great deal of understanding of metacognition has been generated, research results suffered from incongruencies in the use of the construct and its application among various fields. In the quest toward deeper comprehension of metacognition in creativity, creativity researchers may need to approach the construct in a more reflective way. In particular, when metacognition can be seen as imposing rigidity (attention turned outward utilizing a high level of working memory), it may be important to consider how such a deliberate thinking process may use up mental space when space for spontaneous thinking is needed (attention turned inward facilitating creative processing).

Some studies demonstrated a positive association between metacognition and creativity; however, many seemed to lack rigor. In light of numerous studies that examined the relationship between creativity and other constructs such as personality, the field needs more studies on the personality-metacognitive interaction to shed more light on how metacognition affects creativity when personality is included in research. Similarly, the association between motivation and creativity has been well studied, and including motivation in research to isolate the effect of metacognition on creativity beyond the influence of motivation may produce more accurate information. For example, could strong interest and unforced metacognitive regulation result in spontaneous creative activity more so than with weak interest? How metacognitive process is applied to creativity tasks by individuals with certain motivational

tendencies, with certain personalities, with certain thinking styles, and with certain types of instructions is an area where more research is needed.

Application of metacognition also depends on the type of research problems or task nature. Whereas certain tasks may be more motivation- or personality-dependent, others may require metacognitive process at the beginning, middle, or end part of the task completion. The studies of mind wandering seem to have opened up an area in which researchers can explore when, for whom, and for what occasions or tasks, the transition from drifting mind to metacognitive mind can be encouraged to foster creativity. This is yet another challenging but worthwhile research area.

Glossary

Intentionality Making a conscious decision to do something, as is the case when a person consciously decided to question assumptions or shift perspectives.

Meta-art Art which allows the artist and the audience to question the function of art.

Meta-cognition Thinking about thinking.

Meta-creativity The application of what is learned from studies of creativity to the subsequent research on and thinking about creativity.

This *Encyclopedia of Creativity* attests to the progress that has been made over the past few years towards a deeper understanding of creativity. This is the third edition and progress is apparent in the various updates to chapters which were covered in the two previous editions. Progress is probably even clearer in the new topics in this third edition. Many of these focus on technology and creativity, and quite a few focus on the neurosciences and creativity.

The progress is especially impressive because creativity is not an easy subject matter. No wonder Frank Barron, one of the key figures when this field was just starting out, wrote in his last book, *No Rootless Flower*, that to measure creativity (and thus do empirical research on it), some creativity was required. Creativity is a challenge because some of it is unconscious, personal, emotional, and not easy to investigate with methods that work in other fields and work with other topics. Paraphrasing but also broadening Barron's idea, to study creativity requires creativity.

One advantage now available is *meta-creativity*. This may sound like jargon or a buzz word, but the label really is perfectly apt. Consider other uses of the prefix meta. There are meta-analyses, which analyze the results from previous analyses, and there is meta-memory, which is one's memory for what and how one remembers. Meta-cognition is thinking about thinking. Perhaps closest to the current topic are the terms *meta-art*, *meta-drama*, and *meta-theater*. These refer to art that somehow asks the viewer or audience to think about the function of art. Joni Mitchell wrote a song describing how singing is a unique art form (that is, she sang a song about singing), and in the visual arts Warhol's work comes to mind. Shakespeare sometimes had *dramatis personae* in dialogue about actors and acting. Marcel Duchamp was quite explicit about meta-art. He claimed that "The spectator makes the picture" (quoted from the University of California Press <https://publishing.cdlib.org/ucpressebooks/view?docId=ft3w1005ft&chunk.id=d0e6221&toc.id=&brand=ucpress>, downloaded 22 August 2019). The idea of art eliciting reactions, not about the subject matter, but instead about the nature and function of art, is frequently traced to Immanuel Kant's *Kritik der Urteilskraft* [*Critique of Judgment*], and in particular his idea of a *Transcendental Aesthetic*. Schinckus (2019) offers a new look at the philosophy behind this perspective on art and explains how Henri Bergson was also instrumental in developing it.

Meta-creativity is an apt label for *the application of what is learned from studies of creativity to the subsequent study of creativity*. There are clear benefits to meta-creativity and it may be responsible for some of the recent progress in the field of creativity studies. This chapter explores several examples of meta-creativity.

The term meta-creativity was used in the *Journal of Creative Behavior* in 1998, but it had a different meaning from how it is used here. Bruch (1988) used the term meta-creativity but defined it as focused on "internal observations of creative processing and personal characteristics... [that] constitute a new field" (p. 112). That definition might apply specifically to an individual's thinking about his or her own creativity, which is not far from meta-cognition and meta-memory, and it might fit with psychodynamic or humanistic views of how creativity is related to health. This previous usage of the term meta-creativity is clearly different from how it is used here. The earlier usage was concerned with individual and internal processes and the newer usage explored in this entry is about creative methods which are based on what is learned from creativity research and then applied to creativity research in the future.

Meta-Creative Techniques

One of the clearest examples of meta-creativity involves the questioning of assumptions. This is a widely used tactic and has been recommended by numerous researchers and observers. The questioning of assumptions seems to have led to many creative

breakthroughs (e.g., [Root-Bernstein, 1989](#)), so it is wise for creativity researchers to use the tactic themselves. One way of describing the benefit of questioning assumptions is that it opens new doors, suggests new perspectives, and highlights things which were taken for granted in the assumptions. Taking things for granted is often a barrier to creative insights, as are the related barriers involving habits and routines. It may be that the notorious “cost of expertise,” where individuals with large knowledge bases overlook original possibilities, can be explained at least in part by their making assumptions. This is a good example in that it both points to a benefit of questioning assumptions but also relates them to experience and expertise. In addition this example makes it clear that assumptions are not all bad. Experts make assumptions based on knowledge and, for that reason, can process information very quickly. Sometimes the information processing is automatized and details are not considered, which is why the information processing is so efficient. The point is that there are often pros and cons to assumptions. One recommendation from this line of thought is that it may be that tactics and assumptions are useful, but only if the individual is aware that he or she is using them. Intentionality may be very important, if not vital. That actually fits well with many definitions of creativity; many of them recognize the important role of intentions.

Specific Examples of the benefits of questioning assumptions are easy to find. Einstein apparently questioned the Newtonian assumption of absolutes, and the Impressionists questioned the need for realism. Then there are examples from the field of creativity, which is the primary concern of this chapter—being creative about creativity research. The idea of a *creativity complex* can be given as an example, though at first it was an observation based on research results and actively discussed in the research. Donald MacKinnon described creativity as a syndrome, for example, as did [Mumford and Gustafsson \(1988\)](#). The evidence for a syndrome or creativity complex continued to accumulate, the key being that creative performances seem to rely on contributions from cognition, personality, attitude, affect, and perhaps style. At this point the idea of a creativity complex is rarely if ever tested; it operates as an assumption within the creativity research. Yet the meta-creative approach suggests that this assumption should be questioned, which is what the theory of parsimonious creativity is all about. It questions the idea of a complex and follows a logic where all results of the creative process are put aside precisely because they are results of the process and not involved in the processing—what might be called the actual creation. It also relegates mere influences on the creative mechanism, which means that things like cognitive style are put aside. Certainly cognitive styles can influence the actual creation but there are different ways to be creative. No one style is required of all creativity; and in that sense no style is always involved and vital. This approach, which puts (1) results of the creative process and (2) mere influences on the creative mechanism aside, eliminates many things that are usually included in the creative complex. Hence the label, parsimonious creativity. The intent is to simplify and isolate the actual explanatory mechanism that is involved in all creativity. Other details about this view are presented elsewhere in this volume.

Although intentions were mentioned above it is possible that some meta-creativity occurs without much effort. Consider the meta-creative tactic *change perspective*. This is a quite general tactic and may include putting a problem aside for a time and allowing incubation, talking to other people, collecting more information, taking a walk and looking for analogies, or physically changing one’s point of view, as implied by suggestions to zoom in or zoom out, turn the problem on its head, and so on. Many shifts of perspective lead to changes in one’s thinking, and originality may result. As for intentions, note the idea of collecting more information. This is what researchers do when they read other research or collect data; and very likely they also change their thinking as the new information comes in. Thus a new perspective may result from just going through the scientific method. Researchers may not stand back and say “I need to change my perspective” but instead just collect new information and their perspective changes without it being a conscious decision.

Much the same may be said about the tactics that were described by Sidney Parnes, and in particular what he called “let it happen” tactics. These are things people may do to get out ruts, routines, and fixed perspectives. Talking a walk or incubating are two good examples. The person does not impose some problem solving technique but instead gets out of one context and thus relaxes and perhaps broadens associative processes. This kind of thing can be contrasted with what Parnes call “make it happen” tactics. These are more intentional, more effortful, more dependent on particular decisions. Both let it happen and make it happen tactics have been shown to benefit creative thinking, and both could be used meta-creatively by individuals who are studying creativity.

Then there is mindfulness. It too has been supported by creativity research. Ellen Langer has published a series of reports in the *Creativity Research Journal*, and elsewhere, and much of the work is summarized in her book *Mindfulness* from 1989. The general concept of mindfulness is quite relevant to the argument presented here about meta-creativity in that both indicate that it is a good thing to monitor one’s own thinking and to be consciously aware of decisions being made, especially when they influence one’s thinking. Too often assumptions are made mindlessly and they constrain one’s thinking and keep it from being original, fresh, and creative. What is most relevant is probably the idea from Langer’s work on mindfulness that people have a tendency to categorize information. This is natural and often helps structure thinking and experience so searches are efficient; but there is a downside, at least when previous categories of thought are used in new situations and new information is ignored because it does not fit into old categories.

This is enormously helpful when thinking about meta-creativity. Consider the idea of Big C and little c creativity. [Merriotsy \(2013\)](#) reviewed that dichotomy and concluded that it might have been borrowed from studies of culture (where Big C and little c refer to different kinds of cultures)—and thus might not be a good fit for creativity research. Regardless of its origins, it is a dichotomy, and dichotomies can be misleading. After all, reality is complicated. All categorizations are simplifications, and the simplest (and therefore the kind of categorization that ignores the most information) is the dichotomy. The problem with

the Big C/little c dichotomy is that it implies that they are entirely different from one another when in fact the latter may very well be necessary for the former. It may be that an individual must have an original idea, and at first it is a private event. That idea might later be shared, refined, extended, and tested, and sometimes this leads to a major breakthrough. It is not as if eminent creators have one kind of brain that allows one kind of thinking and everyday creators have another kind of brain and another kind of thinking. Certainly eminent creators may be experts, but that means they have mastered a field and are well-informed. They may also be persistent, especially when intrinsically motivated, but that means they are motivated and persistent, not that the kind of thinking used differs from that which allows the rest of us from having an original and effective idea.

The main problem with the Big C/little c dichotomy is that there are gradations of creativity, and variations. Eminent creators may have one major breakthrough and most everything else is only creative in an everyday or mundane fashion. The standards used to classify creativity may vary from world class to entirely local or even personal. Consider the author who writes something but does not share it. It could be original and effective in the sense of capturing that person's thoughts and emotions. Maybe it is shared and one other person sees the creativity. Or perhaps it wins an award at some university. Or is published. Or wins a Pulitzer. Or changes the domain. There are similar gradations in all fields and any one dichotomy is a simplification.

The research on mindfulness suggests that we should remain aware of the categories we use and modify them as new information makes itself known. In the case of research this should be changed to "new information is discovered." The point, however, is to be mindful and recognize the changing and complicated nature of reality. That certainly applies to the topic of creativity and applies to creativity research. As evidence consider the Big C/little c dichotomy that may have been borrowed from research on culture (Merrotsoy, 2013), and gradually became a staple in studies of creativity. Only recently was identified as a false dichotomy. Thus being mindful of categories beyond a dichotomy advanced the creativity research.

One last example of metacreative thinking is suggested by another chapter in this same *Encyclopedia*. This other chapter focuses on the *magic synthesis*. The original conception of the magic synthesis described it as the process whereby primary and secondary processes collaborate, the result being creative. The main point of that chapter was that there are various ways in which creative thinking benefits from syntheses and even paradoxes. The collaboration of primary and secondary processes represents one example of a fruitful synthesis, but there are many others, each of which allows a juxtaposition of opposites or contradictions. The Janusian process is another example [see JANUSIAN, this volume] of cognitive syntheses, but paradoxes are resolved in a creative in personality as well. This occurs when creative individuals express seemingly contradictory traits. They may be both masculine and feminine, for example, or both introverted and extraverted. This has been called the paradoxical personality.

It may be that the capacity to synthesize paradoxes, contradictions, and opposites is tied to the same process which is associated with mindfulness. After all, mindfulness leads the individual to avoid exclusive thinking and to remain open to possibilities that would be precluded by thinking with strict dichotomies and categories.

Importantly, some time ago Frank Barron observed that creative individuals are notably tolerant of contradictions and paradoxes. In fact he described how creative individuals sometimes seek out contradictions and paradoxes because they know that thinking about them often leads to a creative insights. This is why the magic synthesis is included in the list of metacreative options: it can be utilized. Those studying creativity can choose to examine contradictions and paradoxes and in that way find creative ideas.

Conclusions

This entry to the Encyclopedia defines meta-creativity and points to various examples of it. These include changing perspectives, being mindful of dichotomies and categorizations, questioning assumptions, and keeping one's eyes open for paradoxes. This is a tentative list. Other meta-creative tactics may already be in use, but perhaps not named meta-creative, and still others may later be identified, developed, and refined. Admittedly in some cases the benefits of meta-creativity for research are quite clear (e.g., moving beyond the false dichotomy of Big C/little c), but the thesis of this entry does not imply that the creativity research is only advancing because of meta-creative tactics, including those listed above. These meta-creative tactics may be viewed as one option in the research toolbox and one of several reasons why research is advancing.

One possible meta-creative possibility was not discussed above. It involves intrinsic motivation. It was not mentioned earlier, when questioning assumptions and the other metacreative tactics were reviewed, because there is no real recommendation when it comes to intrinsic motivation, other than take advantage of it when it arises. Intrinsic motivation is often associated with creative thinking and with the persistence that characterizes highly creative individuals. It is also associated with the everyday thinking that is involved in personal creativity. This kind of motivation is intrinsic; it is not something that the individual decides to do. People find what is intrinsically motivating. There may be no choice in the matter, in which case the only recommendation is to be aware that what is intrinsically motivating, like paradoxes and contradictions, may lead directly to creative thinking and insights. Creativity is so valuable, in so many different ways! People should invest in it, support and appreciate it, find tactics to facilitate it. Similarly, now that the field of creativity research has established itself and there is a body of research findings, those studying creativity should stand back and use what has been learned specifically to insure that creativity research is itself creative.

Metaphor as a Means to Knowledge

The use of metaphor amounts to explaining the unknown in terms of what we know. This means of gaining knowledge ignores literalism and is often an invaluable resource to understanding certain areas of reality. Such is the case of Boyd's 'constitutive metaphors' in science, in which the construct (stem cells, or the selfish gene theory, for example) cannot be understood but through a powerful metaphor.

However, without reaching such complex epistemological heights, the importance of metaphor in human thinking and discourse is rooted in the extensive use we make of it from an early age, and the presence of so many more or less abstract ideas that we express through metaphor, across a great number of languages and cultures. This is what Lakoff referred to as 'conceptual metaphors': for instance, seeing life as a journey.

To express this concept for everyone to understand, these four words will suffice: "this is like this". Children and adults alike use this fertile mental resource for combining two terms to explain the unknown in terms of what we do know, either through set phrases (to fly like an arrow or as high as the moon) or from our own experience and prior knowledge, matching something familiar to the thing we are trying to explain. In a poetic vein, our forebears gave names to the constellations to establish their positions in the night sky thus forming an astronomical calendar: groups of stars forming an archer, a fish or a crab. This is done simply by applying a talent that is natural to humans: finding similarities between new experiences and what is already familiar to us.

Research on the nature of metaphors and their role in discourse and thinking –and, especially, on their role in creative thinking– has been conducted from the fields of linguistics and psychology. In 1983 Gentner proposed a model to explain analogous thinking: *the structure mapping* theory. According to Gentner, metaphors involve mapping knowledge from a source domain that is known, to a target domain, that is unknown and that individuals strive to explain through the former, shaping a new system of relationships between both source and target in which elements are combined. This combination may contain tiers of complexity: from relatively simple objects or relationships to complex structures as in the case of 'mega-metaphors'. In Niels Bohr's well-known metaphor using the solar system to represent the atom, this Nobel laureate is stating that people can visualise the structure of a hydrogen atom –on a quantum scale– as the structure of a planetary system in which the centre, i.e. the Sun, corresponds to the nucleus of the atom, and is surrounded by planets, represented by electrons spinning around the nucleus.

Lakoff, from a linguistic stance, dismissed the traditional view on poetic metaphor, sustaining that metaphors are not composed merely of words, and that the generalizations governing poetic expressions do not reside in language but, rather, in thought. The conceptual system proposed by Lakoff and Johnson in 1980 introduced the concepts of 'target-domain' and 'source-domain'. The principal function of metaphor is to facilitate understanding of an abstract or unstructured domain by means of another that is familiar or well structured. In referring to the metaphor 'love as a journey', I am using a set of ontological correspondences characteristic of mapping. Again according to Lakoff (1993, p. 207), mapping to define the metaphor 'love-as-a-journey' includes:

The lovers correspond to travellers
The love relationship correspond to the vehicle
The lovers' common goals correspond to their common destination on the journey
Difficulties in the relationship correspond to impediments to travel.

This example fits very well with Lakoff's definition of metaphor as 'cross-domain mapping'.

Differences Between Metaphor and Analogy

Generally speaking, in the literature it is difficult to make a distinction between metaphor and analogy, and these are frequently equated. Thus, for instance, Johnson-Laird saw analogy as a resource that allows explaining a problematic domain of knowledge

(target), through a familiar domain of knowledge (source). The correlation between this definition and those given for metaphor by Lakoff and Gentner is undeniable.

In cognitive terms, both effectively involve the same mental process: a cognitive process to explain the unknown using what is known. An Aristotelian influence is present in this distinction. Aristotle found that analogy is a type of metaphor requiring greater complexity: whereas a metaphor establishes a relationship between two terms (A is B), an analogy involves four terms (A is to B as C is to D). Handbooks in cognitive psychology refer to analogous reasoning, in line with the Aristotelian tradition, and it is considered as a tool for solving problems; wherever individuals seek to understand new situations by establishing a parallel with prior situations we are using analogous reasoning. And when speaking of ill-defined problems, addressed by creative thinking, they fall back on analogous thinking in terms of analogies or metaphors as tools (though not the only ones) to deal with such problems and generate ideas that are original and useful, or in other words, creative.

Although metaphor and analogy both equally imply a mental process of structure mapping, some researchers, nevertheless, explicitly agree (see [Gentner et al., 2001](#)) that metaphors allow for broader variability. Moreover, according to the same authors, while metaphors are more specific and apply to affective-expressive purposes, analogies tend to have more explanatory and predictive uses.

This distinction brings up the classic dichotomy between artistic and scientific creativity: analogies would appear to belong to the world of science and metaphors to that of literature or the arts, in line with the distinction between the quest for truth vs. the quest for beauty.

However, [Romo \(2019a\)](#) found that this rather simplistic trend toward dichotomizing what minds produce: art and science, beauty and truth, emotion and reason, is nothing but a fallacy. Feyerabend, the anarchist philosopher of science (as he called himself) connected science and art, identifying science with myth, claiming that both are narrative forms, constructions built on facts; both interpret and aspire to encompass and explain the two.

Similarly, Lorena Preta in her book on metaphors in science discussed the arbitrary division into two epistemologies, one for knowledge on the natural world, paradigmatic and timeless, and another for gaining knowledge of the human world that is full of subjectivity, intentions and emotions. In addition, “we are increasingly aware that it is not possible to draw reliable conceptual confines between reason and emotion” ([Preta, 1993](#), p. 25).

Many artists and authors envisage their work as a path toward reality, to explain the external or internal world (for instance, surrealism would use the world of dreams as a source of inspiration) and numerous 20th century scientists have referred to the aesthetic experience present in their creative work. As Albert Einstein put it:

It has been said that I have been inspired by Mach's philosophy. It is not true: (...) I have been inspired by something different; in which I believe that the architecture of the laws of nature must have beauty and harmony. And relativity gives it.

Einstein in [Marina \(1993\)](#) p. 325.

The list is very extensive. In the case of Poincaré and Dirac in mathematics, mathematical beauty is a guarantee of truth. In the field of physics, Planck, Michelson or Feynman likewise refer to the beauty of scientific theories. Not to mention the geniuses of the first scientific revolution such as Galileo and Kepler, whose preconception of the aesthetic and the sublime permeated their interpretation of the universe. Kepler attempted to explain planetary orbits around the Sun in terms of a theory of inscribed solids, in which the five perfect geometric shapes defined by Pythagoreans and Plato would explain the movement of the known planets; but observation data obliged him to accept, albeit reluctantly, elliptic orbits. Galileo opposed this vehemently and adhered to the explanation involving circular orbits, simply for aesthetic reasons: it was not possible for celestial bodies' movements to follow such an imperfect figure as an ellipse, which is nothing other than a deformed circle ([Image 1](#)).

At this moment in history, when the disaggregation and compartmentalization of scientific knowledge that peaked at the beginning of the last century has now declined; now that schools are calling for the integration of subject knowledge in order to instil creativity in children; and we are reclaiming the model represented by Leonardo da Vinci, the Renaissance polymath, the dichotomy mentioned above: beauty vs. truth; art vs. science, now seems artificial.

[Root-Bernstein \(1999; p. 368\)](#) spoke of

... reconciling poetry with physics, art with chemistry, music with biology, dance with sociology and any other possible combinations of aesthetic knowledge and analytical knowledge, thus helping people to feel what they wish to learn and to know what they wish to feel.

In this context, the attribution of metaphor to art and analogy to science seems increasingly contrived. Let us explore below which types of metaphor to examine, and their role in creative production.

Image 1 Kepler's platonic solids model of the solar system.

Types of Metaphor

The first classification is the result of a very clear criterion: the distinction between 'metaphors new and conventional', as stated by Lakoff. The most commonly used metaphors are conventional, part of our community's linguistic repertoire, and have become automatic in our everyday use of language. Conceptual metaphors fall into this category. In the metaphor 'love is a journey', Gibbs (2011) offered several possibilities in which English speakers refer to their love relations: we're headed in opposite directions, our relationship is at a crossroads or our marriage was on the rocks. The mental effort required to use these metaphors is limited to the task of recovering from semantic memory, and does not involve the creative task of establishing from scratch a correspondence or mapping between systems of relationships for the two domains in hand.

The same is true in science when metaphors are used in discourse. For instance, when speaking of stem cells, genetic code or black holes; or in psychology, when Freudian terminology is used such as cathexis, latent content of dreams; or with terms coined by William James such as stream of thought; or behavior as motivated by the Lucifer effect or the Pygmalion effect.

A second classification criterion is related to extension. The differentiation between 'micro-metaphors and mega-metaphors', in a classification proposed by Werth (1994) to distinguish localized metaphors used at given points in the discourse to refer to specific content, known as micro-metaphors. Among those mentioned in the previous paragraph, the following are considered to be micro-metaphors: cathexis, latent content, Lucifer effect and Pygmalion effect. Mega-metaphors work on a deeper level, affording greater coherence and depth of meaning to the overall discourse. The theories of selfish genes, black holes or William James' stream of thought clearly belong to this category. In cognitive psychology, the computer metaphor became popular in the 1960s. Though not attributed to any individual author, its transcendence influenced the consolidation of the cognitive revolution and was instrumental in handling the new information processing issues to be addressed under this discipline as opposed to those dealt with for 40 years according to the behaviourist paradigm. The computer-metaphor, just as the selfish gene or the genetic code, are explanatory models that serve as a guideline to establishing the premise for a new theory and a source of recommendations for extending its applicability. Some authors, as pointed out by Ortony (1993) in his book *Metaphor and Thought*, are of the opinion that these type of metaphors would be more aptly described as analogy.

Another important classification for metaphors in the field of science has been given by Boyd (1993), who differentiated between 'pedagogical and constitutive metaphors'. The latter are similar to those described for the mega-metaphor category. The former play a role in the transmission and comprehension of scientific theories: an example is the atom as a solar system, used by Niels Bohr. Constitutive metaphors, however, play an essential role in formulating scientific theories or constructs (the selfish gene, the genetic code or black holes) since without them, according to Boyd, theory is incomprehensible.

In the psychology of science, Darwin's famous image of a 'branching tree of nature' has always been present as a broad metaphor. This image was used at critical moments in the development of his theory, always to express his central argument relating to an organic whole made up of the aggregate of a set of essential parts, whose importance became patent as it was the only illustration in Darwin's *On the Origin of Species*. Gruber described this analogy as a 'image of wide scope', defining it as a pattern that encompasses a wide range of perceptions, actions and ideas and that may be inclusive of further analogies. For Gruber, these are essential components of any theory. In this sense, they relate to Boyd's notion of constitutive metaphor (See Evolving Systems Approach).

Darwin's work, furthermore, is full of other simpler and well-known metaphors, such as war, struggle and selection, that can be compared to Boyd's pedagogical metaphors, and also to the micro-metaphors in the classification by Werth.

William James also used metaphors freely, with a clear descriptive purpose regarding his functionalist conception of the mind: continuity, change, selection, unity and relationships among the elements of thought. According to Osowski (1989), stream of thought also fulfils this 'image of wide scope' role, including others such as chain, train, path, channel, line, etc. and reflects his vision of experiencing the phenomenon of thinking with complex flow as its essential feature (See Flow).

Sigmund Freud, too, borrowed metaphors from the realm of physics to represent the balance of energy and tensions among the three instances of psychic life: the unconscious, preconscious and conscious in his first topic, or id, ego and super-ego in the second topic. In this construct, the hydraulic model afforded him considerable heuristic value and also constitutes a metaphor in the long-range category as seen in the view taken by Gruber and colleagues. Through conducting case studies, these authors showed how metaphors in creative work are never isolated, but operate as articulated groups, sometimes embedded in others with a broader outreach. Only this method makes it possible to analyse their emergence and evolution, as masterfully achieved by Gruber in his book *Darwin on Man*.

Metaphors and Creation

In formulating and solving ill-defined problems, in the search for valuable new ideas in any field, creative thinking resorts to metaphor as a useful heuristic to achieving that goal.

However, depending on the domain, the role of analogous thinking varies widely. Thus, whereas in poetry it is, without discussion, the result of a process: the product itself; in music, other literary forms, fine arts or advertising it may or may not be the product, but will appear systematically throughout the process. This is also true in science, although, strictly speaking, certain forms of scientific discovery, especially serendipities where the role of chance is determinant and metaphor occurs seldom.

By way of an example in poetry, here are verses from *Romance de la Luna, Luna* by the Spanish poet Federico García Lorca, a tale of how the Moon led the child away from the forge, stealing him from the Gypsies. Each stanza holds fine metaphors playing with the white moonbeams as an implicit source domain:

La luna vino a la fragua / The moon came to the forge
con su polisión de nardos / in her creamy-white robe
El niño la mira mira / the child stares, stares
El niño la está mirando / at the moon the child stares

En el aire conmovido / In the unsettled air
mueve la luna sus brazos / the moon stirs her arm
sy enseña, lúbrica y pura, / to show, voluptuous and pure
sus senos de duro estaño. / her breasts of hard tin

Huye luna, luna, luna. / Away, moon, moon
Si vinieran los gitanos, / should the Gypsies come now
harían con tu corazón / they would have your heart
collares y anillos blancos. / to forge white necklaces and rings

A second example is the case of Charles Nicolle who, through auspicious insight recognised the agent that halted the spread of typhus at the general hospital in Tunis. As he told the story, the barrier was the door to the hospital. Automatically, the problem was formulated and ready to be resolved: if within the hospital the disease was not transmitted, but outside it was, then there was something that patients carried with them but did not cross the hospital threshold: louse! This was the mechanism for the spread of endemic typhus, present outside but not inside the hospital. All he had to do was to prove his hypothesis experimentally.

And, thirdly, an examples of serendipitous discoveries free from metaphor is the discovery of penicillin, the planet Neptune, conditioned reflexes and gravitational waves. Nevertheless, despite the absence of metaphor, the discovery cannot be attributed to chance because, as noted by Pasteur, chance favours the prepared mind. In some cases, these are findings that pave the way for the development of complex theories: antibiotics, or the learning theory. In others, they are the necessary consequence of forecasts consistent with a previously developed complex theory. The planet Neptune confirmed an earlier discovery of greater import, namely universal gravitation: if the orbit of the planet Uranus was altered at a point on its path it was because there must be another planet exerting gravitational pull. Gravitational waves have been discovered, also by chance, 100 years after Einstein predicted their existence in his General Theory of Relativity. Speaking of Einstein, it is appropriate to recall here his words in a letter to the mathematician Hadamard, in which he was able to discern, thanks to his introspection, the psychological nature of the mental process in hand: analogous thinking.

Words or language do not seem to play any role in my mechanism of thought. The physical entities which seem to serve as elements in thought are certain signs and images, that are more or less clear, which can be "voluntarily" reproduced and combined [...] This combinatory play seems to be the essential feature in productive thought.

Einstein in Ghiselin (1952), p. 43.

In actively searching for strategies to formulate and solve problems, analogy can provide a rich source of ideas and scientists use it regularly (See analogies). Recourse to metaphor by creators in any sphere is systematic and constant, in one form or another: either as result (this includes not only instances such as the *Romance de la Luna*, *Luna*, but also the complex scientific theories mentioned above). These theories cannot be grasped other than through a defining constitutive metaphor or as instrument, in approaching the formulation and resolution of the problem or as a mechanism for intelligibility, as seen in the classification proposed by Boyd.

The age of logical positivism, in which science is viewed as a literal characterisation of reality expressed through scientific language, is over. In this context, as advised by Ortony, a constructivist approach should be adopted since knowledge of reality is a construct that reaches beyond the information received. The major role of metaphors as a means for gaining knowledge, as discussed here, owes much to the Kantian epistemological position: people construe the world within the restrictions of knowledge and language.

Theoretical proposals for explaining the process stemming from the realm of Psychology of Creativity are closely related to Einstein's words, reproduced above.

Mednick (1976), in his paper *The Associative Basis of the Creative Process* defined his thesis on association in creative thinking:

The forming associative elements into new combinations which either meet specific requirements or are in some way useful. The more mutually remote the elements of the new combination, the more creative the process or solution.

S. Mednick in A. Rothemberg and C. Hausman (1976) p. 228.

It is strongly based on the introspective references of Poincaré who spoke, as did Einstein, of his creative experience in mathematics as a mental combinatory play of mutually distant concepts (See Remote Associates).

Another great architect of combinatory theory in psychology was Arthur Koestler who in his book *The Act of Creation* offered his concept of 'bissociation'. Bissociation is the act of thinking, of connecting independent mutually remote matrixes, of successfully transcending the framework of reference for a given conceptual system and connecting it with a different reference framework. This provides many instances of the use of analogy in science. An interesting precedent, evidently, to the notion of metaphor held by the authors mentioned here though with a rather phenomenological focus and constant recourse to mysterious processes of the unconscious.

In ordinary thinking, according to Koestler, we act within frameworks of reference following logical discourse criteria guided by normally conscious processes. In creative thinking, by contrast, flexible thought processes allow exploration to follow subconscious routes that lead to bissociation in an act of rebellion against the order and discipline of conventional thinking.

Albert Rothemberg coined another neologism to refer to the same thing: Janusian thinking, in allusion to the Roman God Janus, represented with a two-faced head. Creation, too, has two faces, as it implies the ability to simultaneously consider two or more opposed ideas or images during the mental process in which they will be modified, transformed and used for artistic, scientific or other purposes.

The cognitive style known as 'overinclusion' put forward by Hans Eysenck likewise contributes to the thesis of combinatory play, and is characterized by broad associative gradients and extreme generalization of stimuli. The frontiers of meaning for each concept are poorly defined, and, according to Eysenck, this style is common to creativity and psychosis alike, although in creative thinking, as opposed to schizophrenic thinking, a critical assessment is made of the outcome of superinclusive thinking, selecting only the most fruitful associations.

In the systematic and current version of the combinatory approach, an author who made valuable contributions to the discipline of Psychology of Creativity is Robert Sternberg. According to his concept of 'semantic feature spaces' the goodness of metaphors depends on maximising the distance between the two domains involved. A good metaphor uses regions in two remote conceptual spaces. This concept of goodness or 'aesthetic pleasingness' is in contrast with the notion of 'comprehensibility' that requires minimising the distance between the two domains.

Admittedly, it is difficult conducting empirical research regarding how metaphor works in the creative process. Although some studies have been conducted, as in the case of Dumbor with biologists in a laboratory, most research has been qualitative in nature and based on case studies, as in the case mentioned above of the research team led by Gruber.

A final important topic related to the psychological nature of metaphors used in creativity is the relationship between artificial intelligence and creativity. The issue to address is: can computers make metaphors, and if so, what kind of metaphors?

It is clear that this is not simply a cut-and-paste process. Ideas merge giving rise to a new reality. It is possible to create artificial intelligence programs capable of combining concepts. With this type of software, mermaids could be achieved by combining, through algorithms, fish and women, but as noted by Margaret Boden no one would hear their song; only mermaids created by poets sing.

There must be some exclusively human trait in what writers do when creating poems that computers —capable of winning at chess against an expert player, painting pictures that have been exhibited in art galleries or writing more or less bland narrative— cannot replicate in an indisputably creative manner. Perhaps life experience, emotions or human relationships are the source on which the powerful creative heuristic, analogous thinking, thrives.

However, science is much closer to understanding in computational terms and, perhaps, to reproducing, the workings of analogous thinking, as Margaret Boden anticipated 27 years ago in his book *The Creative Mind*. This has come about with the connectionist models capable of replicating more accurately the workings of the human brain. Parallel distributed processing software produces a form of visual representation on a system-wide activity pattern, in which connections are weighted according to their likelihood. This means that, when two units are active simultaneously, they will adjust their connection weights to raise the likelihood of becoming simultaneously active in the future, too. Moreover, these programs that are more “analogous” to the human mind still do not function according to explicit rules specifying which contents should necessarily become connected.

The advances made in artificial creativity cannot be denied. In 2017 Elgammal et al. presented the *Creative Adversarial Network* for generating art. This system generates art by viewing art (accessing 80,000 works) and learning different styles. The program is equipped with a generator able to create novel works with stylistic ambiguity whose artistic value lies in their arousal potential that deviates from learned styles. This arousal is conceived by the authors as a form of artificial motivation.

However, AI has not yet acquired the capacity to produce any work that can be described as ‘eminent’ or ‘big creativity’ or, in the words of Boden, to conduct transformational creative activities. This capacity is hindered by the lack of an algorithm capable of breaking previously established algorithms. This is one of the reasons why AI products are unable to reach big creativity levels: the software programs are constrained by their operating algorithms. Human beings, by contrast, are endowed with such set-breaking capacities, the ability to exit conceptual spaces and create other new ones according to previously unknown rules, and can break paradigms to build new ones.

On the Utility of Metaphor

The opening of this chapter gives a clue to understand the greatest value that metaphor holds for human beings: it is a way to approach and learn about the world, to expand knowledge by explaining the unknown in terms of the known.

Rumelhart (1993) stressed the importance of metaphor as an essential ingredient in language acquisition, already present in early stages of development and a natural linguistic phenomenon. By applying familiar words to new objects or situations, infants extend their knowledge sometimes with conventional metaphors and sometimes creating new ones that adults will correct to a greater or lesser extent. But since in creativity productive and critical thinking go together, at a later stage in this evolution, when children are between the ages of 6–8 and 10–12 years, they learn school and out-of-school rules. Children develop critical and evaluation skills, and the quest for realism negatively affects their earlier capacity for metaphor. Gardner calls this period the ‘literal stage’ in which children gain with the incorporation of rules and normative knowledge while at the same time suffering a loss in their metaphorical thinking and tolerance of fantasy.

Across the various domains of creative output the role of metaphor varies. Thus, throughout the arts in general, metaphor contributes to the capacity to convey emotion and aesthetic sensations that the works of great painters, musicians and, in particular, gifted poets awaken in us.

Scientists themselves perceive aesthetic sensations that are perceived too by scholars immersed in studying the complex theories presented through the use of constitutive metaphors. In science, however, perhaps the greatest utility of metaphors falls to those Boyd described as pedagogical, i.e. metaphors that convey and render comprehensible complex knowledge. Metaphors used by authors through the history of psychology to explain the phenomenon of creativity include the following concepts: inspiration, enthusiasm, incubation, illumination, breaking frontiers or synthesis of opposites.

In addition to conveying knowledge a further function of metaphors in science includes persuasion this function aims to convince the scientific community of its own importance. However, this entails the danger of discourse becoming hollow and unproductively rhetorical, as warned by Sokal and Bricmont in their work *Intellectual Impostures*. They accused some authors of inappropriate use, in the field of social science, of metaphors taken from natural science, presumably to achieve on the one hand a more prestigious image, and, on the other hand, to deflect attention from any potential conceptual or empirical shortcomings in their discourse.

To follow on with this argument, there is the further noxious effect of some metaphors in the history of science. The animist view of nature upheld for centuries, a legacy of atavistic anthropomorphic explanations of natural phenomena occurring in myths, held back scientific advancement. For instance, the belief in the ‘horror vacui’ of nature competed for a time with Torricelli’s theory of atmospheric pressure to explain the effects of suction pumps to obtain water from a well.

In a more pragmatic sense, where metaphors are found to register the greatest economic value is in advertising, design and innovation within organizations. TV during prime viewing time bombards the viewer (to use a military metaphor) with advertisements that attempt persuasion by deploying metaphors, more or less aptly chosen, in their spots (See advertising).

Moreover, the production techniques for creative ideas applied in these fields are based on metaphors, their production and their evaluation and selection. The *Synectics* technique devised by William Gordon considered converting the strange into familiar and the familiar into strange as a strategy, and the procedure consists in mass producing metaphors in any of four types: personal, direct, symbolic and fantastic. *Synectics* provokes new approaches: to see familiar things as strange, so that previously concealed

dimensions are perceived or to see new things as familiar and to explain them through known principles and relations. All this leads to producing novel ideas that are useful in dealing with ill-defined problems in the mentioned fields.

It is not so easy, however, to find the right metaphor in any field. As mentioned earlier, cut-and-paste will not work. Not everyone, after the literalism stage, recovers their free and productive childhood thinking that allowed them to find relationships among things. Sometimes, this capability simply fades and becomes atrophied over time. Some people are simply unable to see familiar shapes in the clouds and, from here to the poems of Garcia Lorca, there is a wide gap to fill. There is a bidirectional relation between creativity and analogous thinking, which is why this mental function should not be overlooked in education.

Fairweather and Cramond (2010) emphasized an interdisciplinary approach and teaching for transfer, promoting the use of analogies; i.e. space exploration with the discovery of the New World. Using pedagogical analogies facilitates the learning of new things and new concepts.

Creativity in education can be both a tool and as a target: teaching methods based on a creative model and aiming toward educating more creative individuals; and in this aim, training in analogous thinking should be a priority in schools and at university (See Creativity in the Classroom).

Introduction

An indisputable fact about the digital era is that progressive technology advancements serve as a catalyst for many changes and are thereby changing every aspect of our lives. Technology requires employees to work longer and faster and to be constantly connected; as such, technology can be regarded as invading the personal lives of employees. Moreover, in today's increasingly dynamic work environment, employees often face complex and non-routine challenges; therefore, they are expected to be more creative (i.e. to generate novel and useful ideas).

However, technology has not only impacted the nature of work; it has also shaped the development of a new generation of millennials, also known as "Generation Me," "digital natives" and "Generation Y." As the fastest-growing segment of the workforce, expected to comprise 35% of the workforce by 2020, millennials seem to be invading workplaces. Through their exposure to digital technologies, millennials, relative to people from previous generations, have developed higher expectations about their work, especially about its meaning and purpose. Further, they are seeking out organizations that reflect their personal values and capitalize on their strengths, enabling them to use their talents and creativity to do what they do best, providing them with possibilities to learn and develop and, most of all, providing them with jobs that match their personal lives.

The popular press widely assumes that millennials are not loyal to their organizations and have no problems switching employers if their needs and expectations are not met. Millennials are not willing to adapt their lives to their work but, instead, prefer to adjust their work to square with their life expectations. Studies also suggest that millennials' values and preferences differ from those of workers from previous generations and that these value differences may decrease the effectiveness of current efforts to amplify employee creativity. Millennials are thus forcing companies to adapt and remove long-established traditional workplace structures and policies to engage, manage and retain millennial workers and to exploit their creative potential.

Despite the fact that millennials are one of the greatest assets of future organizations, the organizational literature is relatively silent about how millennials' prevailing characteristics will influence their creativity at work. Therefore, the aim of this chapter is to deepen our understanding of how work environments can be redesigned to better suit millennials' needs, thereby boosting their creativity. Specifically, we explore how work environments might be redesigned to take advantage of millennials' talents to provide meaningful work, enable them to experience the required work-life balance, and thereby increase their creativity.

Millennials' Invasion of Workplaces

The general impression is that millennials' salient characteristics, values and work expectations represent a radical change; this begs the question of whether current workplaces whether current workplaces and systems are equipped to accommodate the needs and expectations of this digital generation of workers. According to [Hershat and Epstein \(2010\)](#), it is crucial to strike the right balance between expecting millennials to adapt to current organizations and adapting organizations to better suit them. Thus, scholars and practitioners must overcome the challenge of rethinking and redesigning work to align it to the needs of incoming digital-generation workers. In what follows, we describe millennials' characteristics and work expectations, which set this generation apart from previous generations. Based on these distinct characteristics and work expectations, we present a (millennial) expectations-based revision of the job characteristic model (i.e., the "it's all about me" model) that promotes creativity and other organizationally relevant outcomes (see [Fig. 1](#)).

Figure 1 "It's all about me" model.

Millennials' Characteristics and Work Expectations

Millennials, those born between the early 1980s and the late 1990s, grew up in a fast-paced, technology-dominated society and are thereby more technology-savvy than members of previous generations. These incoming employee cohorts are more digitally adept and attuned than previous cohorts (e.g., baby boomers, Generation X). Digital technologies—computer hardware, software, smartphones, the Internet and networks—are an integral aspect of their everyday lives. Therefore, they are fluent in the digital language and completely immersed in technology. According to the World Economic Forum, on average, Millennials spend more than 7 h a day online. They have natural ability that they have honed into formidable skills in the use of new technologies. Moreover, millennials' thinking and information processing is fundamentally different from that of previous generations.

Millennials are stereotypically characterized as individualistic, self-centered, optimistic, entitled and disloyal. They are considered to have higher levels of self-esteem than members of previous generations, along with an external locus of control, and they are extraordinarily confident in their abilities. Although empirical research confirms that they are extrinsically motivated, intrinsic values, such as learning and development, have also been identified among millennials' top work values. Millennials have been raised in environments that are rich with feedback, individual attention, praise and guidance (Hershatter and Epstein, 2010); therefore, they expect such treatment in the work environment.

In addition, even in the context of work, they are focused on their individual development; millennials seek career advancement, looking to embrace a challenge and thereby develop new skills. That said, they are described as an intelligent, informed, open-minded and responsible generation that enhances organizational speed and efficiency. However, they are also perceived as demanding employees, who often express their opinions: they have a low tolerance for boredom; they thrive on new challenges; and they value respect, recognition, involvement, fairness and supportive management. For millennials, work is "no longer a place you go, but a thing you do" (Thompson and Gregory, 2012, p. 242); therefore, they insist on freedom of choice, preferring to work when, where and on what they choose. Therefore, millennials will more likely take the initiative to craft their work to reflect their values, needs and passions. Thus, they are aligning their working environments with their work expectations (e.g., establishing a good work-life balance, being involved in challenging, meaningful work and having fun at work).

Building Blocks of Millennials' Creativity

Millennials are considered to be creative; however, they must be engaged in meaningful work that allows them to use their creativity and passion to create value (Espinoza and Ukleja, 2016). Research has demonstrated that good work-life balance, meaningful work, challenging work, job crafting opportunities and entertainment can contribute to millennials' loyalty, retention and creativity, prompting them to bring waves of talent and technical expertise to their work in ways that benefit their organizations. To capitalize on millennials' creative talents, organizations should create work environments that facilitate the personalized motivation required

by millennials and thereby maximize their potential. [Deloitte's survey \(2017\)](#) showed that millennials strive for connections between past and future workplace settings, combining freelance flexibility and full-time stability. We therefore argue that to enhance millennials' creativity, work should be aligned with millennials' expectations. In what follows, we present the future job characteristics that will facilitate such an alignment. Specifically, we first describe the core job characteristics and then introduce free mobility (i.e., the opportunity to move freely and easily) as an important job element that enables millennials to satisfy their need for free stability (i.e., freedom and stability), thereby boosting their creativity.

Core Job Characteristics

Millennials strive for work they perceive as meaningful, indicating that they expect to choose their work and set the terms under which they will engage in their work. Work environments should therefore provide opportunities for millennials to craft their jobs and to change their work to align it with their preferences, motives, skills and abilities. According to [Berg et al. \(2010\)](#), individuals craft their jobs to create opportunities to work on enjoyable and meaningful tasks by: (a) devoting more attention, time, and energy to such tasks; (b) taking on additional tasks that provide enjoyable and meaningful experiences; and (c) reframing the social purpose of individuals' work to align with individuals' purpose-driven experiences. As millennials expect flexible working arrangements that will allow them to take a work deferral to explore their passions, we argue that job crafting opportunities must become one of the core future job characteristics that can be understood to increase millennials' creativity.

Further, job characteristics significantly contribute to the extent to which employees invest more of their time, effort and skills into their work. [Oldham and Hackman \(2010\)](#) argue that significant motivational factors that promote desired psychological states (i.e., experienced meaningfulness of work, responsibility for work outcomes and knowledge of results) include the following job characteristics: greater skill variety, or "the degree to which the job requires a variety of different activities in carrying out the work, involving the use of a number of different skills and talents of the person" (p. 464); task identity, or "the degree to which the job requires doing a whole and identifiable piece of work from beginning to end" (p. 464); task significance, or "the degree to which the job has a substantial impact on the lives of other people, whether those people are in the immediate organizations or the world at large" (p. 464); autonomy, or "the degree to which the job provides substantial freedom, independence, and discretion to the individual in scheduling the work and in determining the procedures to be used in carrying it out" (p. 464); and job-based feedback, or "the degree to which carrying out the work activities required by the job provides the individual with direct and clear information about the effectiveness of his or her performance" (p. 464). We argue that, for organizations to capitalize on millennials' creative talents and potential benefits, core job characteristics should be aligned with their work expectations. Namely, millennials will bring all their skills, traits and knowledge to the workplace; however, they seek the best return for their input of time and energy, and they require job autonomy, freedom, flexibility and meaningful and challenging work ([Aruna and Anitha, 2015](#)). As Millennials value personal development, they must have the opportunity to engage in a number of activities that will allow them to use a broad range of their skills and talents (i.e., have the opportunity to use different skills on a variety of tasks), including problem-solving, team collaboration and technical skills. They also seek out creative challenges; therefore, organizations should continue giving them challenging tasks to prevent boredom. Once millennials master their jobs, they have no problem finding another challenge by switching their jobs ([Lyons et al., 2015](#)). However, it is important to note that millennials also have a strong preference for clear guidelines, structure and systems that support their needs. Although they confidently complete their work from start to finish, along this path, they expect detailed instructions on how to complete their tasks. Thus, we argue that when their core job expectations and needs are met, Millennials are willing to accept some potential constraints of the workplace and are able to find ways how to work with and within them.

Free Mobility Within and Outside Organizations

Digitalization has enabled employees to work at times and places that are convenient to them and facilitate their work-life balance expectations. Gallup's recent 2017 survey on the State of the American Workplace, using data collected from more than 195,600 U.S. employees, confirmed that respondents (especially millennials) are focused on their lives, not only on their jobs. One important consideration among highly talented employees, when negotiating for jobs, is remote working and flexible vacation policies; in millennials' eyes, this enables work-life balance and travel while they hold a full-time role at work. Remote working provides a release from the restrictions of office based hours ([Grant et al., 2013](#)), which has a positive impact on Millennials' perception of work-life balance. However, it is also important to note that remote technology also provides ease of access to work and organizations now often expect employees to keep in touch with work both inside and outside of work time ([Grant et al., 2013](#)). Scholars also argue that technology-driven changes have blurred the boundaries between work and non-work life domains and created a need to renegotiate the relationship between employees and organizations.

Organizations thus face the challenge of how to restructure organizational work to make it suitable for millennials' work preferences and needs and re-establish the relationships between employees and organizations in the digital era. We argue that organizations should provide free mobility opportunities (i.e., opportunities to freely move within and outside organizations) and thereby provide millennials the flexibility required to obtain personal and professional satisfaction. Given that millennials expect a workplace with no boundaries and a fun atmosphere that allows them to be entertained at work, we argue that their work expectations enhance the development of free mobility within organizations. For example, to enhance millennials' creative talent, Silicon Valley tech companies, in addition to monetary awards, provide various perks, such as gyms, swimming pools, different indoor and outdoor courts, video games, places to sleep or rest, free meals and free (or subsidized) services, such as dry cleaning, massages,

health and dental, haircuts, the option to bring their pets to the office, etc. Thus, they attract and retain the best millennials. For example, the pioneer in the field, Google, offers quite a lot of free mobility within the company, enabling employees to move to new teams, projects and departments and spend some time working on individual projects, outside of their day-to-day tasks, that interest them (Hartmans, 2017).

Moreover, for millennials, the work environment is a place to learn, collaborate and socialize; they therefore want to work in a comfortable and socially enhancing environment (Aruna and Anitha, 2015). Organizations are thus restructuring their work environments to make them more suitable for the millennials generation. For example, Airbnb employs a global head of employee experience and goes beyond creating experiences central to the “place of work” (such as access to gym facilities, free massages and gourmet food), making the workplace an experience where “all the elements of work—the physical, the emotional, the intellectual, the virtual, and the aspirational—are carefully orchestrated to inspire employees” (Meister, 2015). Airbnb offices are designed on the basis of employee input in how they want to work, which even extends to allowing employees to design some of the meeting rooms on their own. The spaces are meant to be welcoming so employees feel like they are at home, and meeting rooms are inspired by travel (designed as replicas of the places they offer on the platform), crafting an environment where they can belong anywhere. Companies are also introducing new ways of working, like no-meeting days (e.g., no-meeting Wednesday), devoting one day of the week to core activities and providing time for thoughtfulness and productivity without the interruptions of time-consuming activities.

We further argue that, for millennials, the aforementioned practices are not enough. This is to say that millennials also strive for freedom, mobility, flexibility and autonomy outside organizations. Consequently, based on the expectations of millennials, we are witnessing the rise of several different innovative work design practices, which enable greater work-life balance, satisfaction and personal growth, while strengthening inter-organizational connections, engagement and trust. By giving millennials the option to work remotely, organizations increase employees’ well-being, including their work-life balance, and lower stress levels, while reducing costs and enhancing creativity and productivity. Therefore, increasingly more multinationals (e.g., Apple, Disney, American Express, Xerox, Intuit, etc.) are providing a chance for remote working, following the motto, “If you want people to do great work, let them. And stop caring about where they do it.” (Outsite, 2017). Millennials expect to have the freedom to work when and where they choose; however, at the same time, they also require stability, clear structure and guidance. Thus, co-working spaces may also be appealing to millennials. Co-working places are built around the idea of community-building and sustainability, and address the needs of independent professionals with different knowledge backgrounds (and work-life characteristics of freedom and independence) to overcome the feelings of isolation and loneliness when working from home. The purpose of these places is to create a community, composed of likeminded value-oriented (rather than competition-oriented) intellectual workers in the knowledge economy, and give the members of that community the opportunity to network and connect with a greater intent of developing potential business ideas. There is a high degree of trust among community members, as co-working spaces may be seen as microclusters of individuals, where those individuals (and, similarly, organizations within industrial clusters) can pool their knowledge and create network relationships to co-create and collaborate on various activities and projects. Co-working places thus address millennials’ needs, by employing nomad working practices, with an aim to combine work and leisure within the new era of reputation-based social capital.

Further, some argue that rapidly changing technology enabled instant communication and has, consequently, produced digital nomadism, which is characterized by work mobility and/or leisure and a tendency to change. Specifically, the new digital era employee’s wish for autonomy, independence, work-life flexibility and the pursuit of a meaningful career, while traveling and exploring the world, are a driving force for millennials. On the other hand, this kind of work also enables economic stability, as it can reduce costs of living by allowing employees to stay in cheaper countries around the world. By establishing autonomy, flexibility and excitement outside of work, digital nomads have cracked the code on maintaining work-life balance. Digital nomads are a new generation of employees, who combine travel with the ability to work anywhere, anytime, and may indicate the development of future ways of working. As digital nomadism facilitates enjoyment, allows individuals to take advantage of their knowledge and skills and enables a good work-life balance, it is very attractive to millennials. Digital nomadism may also be perceived as a creative break, where individuals have time to discover more work-life balance. Digital nomadism is also interesting for millennials who have settled for the option to work from anywhere, and freelancers involved in high-tech activities such as coding.

Some millennials seek, from time to time, to escape their daily corporate routine, but don’t feel comfortable with the nomad lifestyle. Thus, the concepts of remote work and co-working developed even further, to encompass co-working hospitality businesses that enable interaction and creation of a community of like-minded professionals, who play as hard as they work, while enjoying great work-life balance. Outsite is an emerging co-living, co-working community that has, to date, established its hospitality businesses in more than 12 locations around the world. The idea of Outsite is to create a work-away-from-home destination, where people can get work done and have fun in inspiring locations around the world. Outsite’s founder described the company as a “hub of entrepreneurial activity and the launching off place for new ideas from leaders looking for inspiration in a place where they can work and escape into nature ... I came up with the idea of combining all the elements that facilitate work-life balance into a co-working hospitality business intended to establish a community of like-minded professionals who play as hard as they work, guests who are as passionate about the concept as we are” (Guisset, 2015). Studies suggest that millennials prefer work that provides more vacation time. Thus, the opportunities co-working hospitality businesses provide may enable them to take some kind of (daily, weekly, monthly) personal retreat and to take off from standard work, thereby achieving a good work-life balance.

Outsite houses also host company retreats, where employees of one company live and work together for a couple of days to boost their creativity and strengthen their relationships. These houses may be defined as places where professional adults can live while on business or personal travel and meet like-minded people (traveling as students would, living in hostels and meeting like-minded backpackers). Outsite has, so far, attracted several types of remote workers, including designers, developers, entrepreneurs, artists and academics from renowned companies, such as LinkedIn, Google, Facebook, Zynga and more. Team retreats and “workations” are designed to promote interaction among employees and the building of strong relationships. As noted above, Millennials perceive work environments as opportunities to meet new friends and build strong relationships; thus, they appreciate such initiatives. Further, team retreats help companies strengthen their cultures and allow employees to connect in more meaningful and powerful ways, returning to normal work more relaxed and excited. These retreats are most effective when joined with other possibilities of new ways of work, such as remote work or “workation” opportunities, where employees have the freedom to choose where and when they work, offering them the option of being on vacations while working.

Individual and Organizational Outcomes

The job characteristics theory posits that the following three psychological states, which employees experience, generate desirable organizational outcomes: employees must perceive their work as worthwhile, valuable, or important (i.e., experience the work as meaningful); they must feel personally accountable for their results (i.e., experience personal responsibility for work outcomes); and they must know and understand (i.e., knowledge of the results) how effectively they are performing their jobs (Kulik et al., 1987). These psychological states are highly relevant for millennials, as they want to engage in meaningful work, are highly confident in their ability to achieve established goals, and expect and appreciate immediate feedback. Thus, organizations are faced with the challenge of creating working environments that their employees will perceive as satisfying.

Studies have indicated that millennials are demanding; they want to choose their work tasks and the conditions under which they will engage in their work. Millennials, also known as “Generation Me,” are more self-focused, have high expectations and self-esteem, and display higher levels of narcissism. Thus, we argue that, although experiencing the abovementioned psychological states is highly relevant to millennials, millennials’ expectations–environment fit should be a central feature of future job designs. Namely, Millennials will most likely proactively redesign their jobs to experience the abovementioned psychological states. However, this generation expects supportive work environments that meet their expectations. They are willing to sacrifice their time and energy for work as long as doing so furnishes them with personal benefits (i.e., if their expectations will be met). If their expectations are unmet, millennials tend to leave the organization within 8–12 months. Thus, to embrace talented millennials and to ensure that they will benefit their organizations, organizations should pay more attention to millennials’ personal outcomes. We argue that the aforementioned building block of millennials’ creativity (i.e., free stability, consisting of core job characteristics and free mobility) increases the likelihood that millennials will be satisfied with their work contexts and have their expectations met (i.e., to achieve personal benefits).

Flexibility (in terms of flexible working hours and flexible working locations), stability and autonomy are the most important factors for millennials when they are looking for work; these factors are linked to improved personal satisfaction, which in turn leads to increased creativity, organizational performance, loyalty and employee retention (Deloitte, 2017). To promote millennials’ creative performance and higher retention rates, organizations should create work environments that provide millennials with the flexibility needed to balance their personal lives and development, leisure and community activities.

We argue that personal outcomes will increase millennials’ work engagement, defined as “the positive, fulfilling, and work-related state of mind that is characterized by vigor, dedication, and absorption” (Schaufeli et al., 2002, p. 74). Vigor refers to “high levels of energy and mental resilience while working, the willingness to invest effort in one’s work and persistent even in the face of difficulties” (Schaufeli et al., 2002, p. 74). The more personal benefits millennials receive from work, the more time, energy and effort they are willing to invest in work, thereby indicating higher levels of vigor. Further, dedication is described as having “a sense of significance, enthusiasm, inspiration, pride, and challenge” (Schaufeli et al., 2002, p. 74). By meeting millennials’ expectations, organizations will increase their dedication to work. Namely, as noted above, millennials value meaningful and challenging work. Finally, absorption is defined as a “state of being fully concentrated and deeply engrossed in one’s work, whereby time passes quickly, and one has difficulties with detaching oneself from work” (Schaufeli et al., 2002, p. 74). As long as work yields personal benefits, millennials will show high levels of absorption. This is to say that, when involved in meaningful work, millennials can prove to be hardworking and highly creative.

Further, high work engagement leads to positive outcomes, such as organizational commitment and decreased turnover. Research shows that millennials are likelier to leave their organizations if they lose a sense of absorption, enthusiasm, meaningfulness and challenge in their work. In addition, it has been noted that millennials can be retained when their expectations regarding their working conditions, how interesting their work is, work-life balance, job security and whether they receive adequate levels of information are met. Thus, we assume that the higher the personal benefits, the higher the loyalty to the organization, and thus, the lower the turnover among millennials. Finally, studies have suggested that if millennials experience high levels of responsibility, work meaningfulness and personal fulfillment at work, this leads to higher levels of organizational performance. Thus, by increasing millennials’ personal outcomes, organizations can maximize their creative performance. Taken together, as depicted in Fig. 1, we further argue that personal outcomes are positively related to organizational ones. Specifically, to retain millennials and capitalize on their intellect and talents, jobs should be designed in such a way as to meet their unique expectations.

Conclusions

In this chapter, we address the question of how to stimulate the creative behavior of millennials, who bring their unique values into the contemporary workplace. Specifically, to explain why and how organizations should adjust work environments to boost millennials' creativity and other organizationally relevant outcomes, we have developed a model that integrates and extends the literature of millennials' characteristics and work design. To capitalize on millennials' talent, organizations should create environments that will satisfy their need for both stability and freedom. We thus developed the "It's all about me" model, in which we introduce the building blocks of creativity that provide the required free stability, consisting of seven core job characteristics (i.e., skill variety, task identity, task significance, autonomy, feedback, social attributes and job crafting opportunities), and free mobility within (i.e., employee perks, the workplace as an experience) and outside of organizations (i.e., remote working, co-working spaces, digital nomadism, co-working hospitality business, team retreats and workations). We further argue that free stability facilitates personal outcomes (i.e., met expectations and satisfaction with the work context), which in turn promotes positive organizational outcomes (i.e., creativity, engagement, decreased turnover, and increased performance).

Given that digital technology will continue to grow rapidly, researchers can make a more significant practical difference by examining how existing work-related systems may be adapted to become more suitable for new, technology-savvy generations. By introducing a set of millennials' expectations that should be considered when designing their work, the "It's all about me" model takes a step toward understanding when and under which working conditions organizations can capitalize on millennials' creative talent. Specifically, digitalization has shaped millennials' work expectations, values and preferences, which have radically changed, relative to those of previous generations. Because millennials are the most educated generation ever, they have the potential to become the greatest assets to the organizations of the future. For this to happen, job structures should be designed in such a way as to enrich the lives of millennials, thereby decreasing their turnover intentions and enhancing their creativity. Along with the suggestion that future job design characteristics should be aligned with millennials' work expectations, the "It's all about me" model also highlights the interplay between the meeting of millennials' work expectations and organizational outcomes. By accounting for how personal outcomes can influence positive organizational outcomes, the "It's all about me" model reinforces the value of investigating how work environments that enable personalized motivation affect creativity, engagement, performance and decreased turnover (i.e., positive organizational outcomes).

Moreover, recent research indicated that millennials aspire to have flexible work environments (in terms of hours and location) and stable financial resources. In the past, this combination appeared impossible; however, recent organizations addressed this need by introducing several solutions offering some sort of location independence and financial stability at the same time (i.e., free stability). The most up-to-date organizations apply hybrid approaches (i.e., combining various options for flexibility, such as remote working, company retreats and workations) with a large degree of autonomy concerning where and how to work (employees' having their own working spaces, places that support interaction with coworkers and the option of working where they would like to work) (Gallup, 2017). This chapter introduces seven core job characteristics and free mobility within and outside of an organization as the building blocks of creativity. These building blocks enable almost any organization to create a work environment that promotes free stability, thereby allowing millennials to achieve the balance they need between their personal and professional lives, thereby boosting their creativity. Taken together, the "It's all about me" model suggests that, to increase positive organizational outcomes in the digital era, job design must expand beyond the organizational context and incorporate millennials' work-to-live philosophy of life.

Introduction

“Stream of consciousness” was first coined by William James, who is often considered the father of American psychology. He indicated four Characters of Consciousness in his thesis:

- 1) Every “state” tends to be part of a personal consciousness.
- 2) Within each personal consciousness states are always changing.
- 3) Each personal consciousness is sensibly continuous.
- 4) It is interested in some parts of its object to the exclusion of others, and welcomes or rejects—chooses from among them, in a word—all the while (James, 1892).

Thus, consciousness has two distinct characteristics—continuous and changing, meaning that our thoughts rarely stay still. Everyone has experienced these kinds of situations: When in a meeting, the TV show that we saw last night pops up in our minds; while doing exercise, we involuntarily imagine the relaxation of the weekend. This phenomenon is called “mind wandering” and refers to the attention shift away from a primary task and toward internal information unrelated to the task. This can include daydreams about fictional worlds, as well as memories and prospective thoughts (Smallwood and Schooler, 2006). Mind wandering is a kind of experience in the “stream of consciousness”; it may appear both in the middle of a goal-oriented task and in a resting state, taking over the individual’s center of consciousness and filling in one’s “stream of consciousness.”

Although it has been a few decades since mind wandering has drawn the attention of mainstream research, this notion has been found in different fields of study in recent years with increasing frequency. As a result, mind wandering is referred to in different ways, such as daydreaming, off-task thinking, task-unrelated thought, stimulus-independent thought, and spontaneous thought. Researchers have found that the frequency of mind wandering in a task is between 15% and 50%, with the least amount of mind wandering occurring during a coding task (15%), and the most occurring during a signal detection task (50%). One study using a large sample was published in *Science* in 2010 and showed that the occurrence of mind wandering in daily life is as high as 46.9%. In this study, 30% of subjects experienced mind wandering in almost all activities (Killingsworth and Gilbert, 2010).

Mind wandering is ubiquitous and it occurs in almost all forms of activity. In traditional research, mind wandering has always been considered the enemy of concentration. In some contexts, such as when driving, mind wandering can even threaten an individual’s safety. Researchers have found that one of the most common contexts for mind wandering to take place is reading, and that mind wandering can significantly impair an individual’s reading comprehension. In addition, mind wandering has often been associated with an unhappy mind, especially when individuals were ruminating on the past.

However, in recent years, a number of researchers have attempted to delve into the positive aspects of mind wandering. Mind wandering has long been associated with an individual’s goals and considered conducive to an individual’s future planning or autobiographical planning. In 2013, Smallwood and his colleagues used an inter-temporal discounting task to examine how mind wandering changes with the amount of time participants are willing to wait for an economic reward. The results indicated that mind wandering is also involved in successful management of long-term goals, and facilitating healthy decision-making (Smallwood et al., 2013).

According to recent empirical evidence, many researchers believe that mind wandering might also contribute to creative cognition. According to their theories, as the mind wanders, remote associations are brought together into consciousness and, thus, mind wandering is likely to play an important role in facilitating creative breakthroughs.

Thus mind wandering can occur at a cost in some cases, but it may also have some potential adaptive functions.

Theories of Mind Wandering

The Executive-Control Theory

In 2006, Smallwood and Schooler proposed the *Executive-Control Theory*, indicating that mind wandering consumes executive resources in the same way as current tasks. This theory was supported by empirical evidence. First, the tasks relying on controlling processes would inhibit an individual from experiencing mind wandering. Antrobus et al. (1966) discovered in a simple signal detection task that the frequency of mind wandering would decrease if the stimulus presentation rate increased. A subsequent experiment also showed that the frequency of mind wandering would decrease as the demand for a subject's working memory capability increased. Thus, it was concluded that mind wandering and tasks were competing for an individual's limited working memory resources, and that, when the resources required by tasks increased, the frequency of mind wandering would decrease. Second, researchers indicated that the longer a task was practiced, the more the frequently mind wandering would occur. A reasonable interpretation was that practicing lowered the demand for attention in skill-based activities. As the individual was getting more familiar with the task, the demand for execution of and control over the task was reduced, fewer executive resources would be allocated to the task, and the frequency of mind wandering would increase. Smallwood and Schooler proposed that mind wandering was a process of dissociation, which transferred cognitive resources from external stimuli to internal information and therefore required the executive control resources to coordinate and integrate the relevant information. However, this theory did not seem to apply to the phenomena where people with high working memory capacity experienced a relatively low frequency of mind wandering when performing tasks that had a high demand for cognition.

The Executive Failure Account

In 2010, Mcvay and Kane proposed the *Executive Failure Account*, an integration of multiple views, challenging the *Executive-Control Theory* mentioned above. They believed that mind wandering was activated automatically, but that it neither consumed executive resources nor relied on the same cognitive mechanisms as execution and control. Instead, mind wandering reflected an executive-control failure, i.e. failure to suppress the generation and maintenance of irrelevant thinking. The function of the executive system is to adjust and maintain external attention through resisting distracting stimuli from both inside and outside; if it failed, the frequency of mind wandering would rise. According to this theory, mind wandering was an epitome of failure to stay focused on task objectives. When the demands of tasks (such as the stimulus representation rate and memory load) increased, the decrease in mind wandering frequency reflected that the control and processing system was resisting interference, rather than taking up executive resources. An individual with high executive capacity is more capable of completing the tasks accurately when compared with others, so mind wandering was less frequent. Mcvay and Kane pointed out that this theory explained performance under fatigue and drunkenness. The *Executive-Control Theory* put forward that in severe fatigue and drunkenness, the executive control resources that mind wandering required were inadequate, so the frequency of an individual experiencing mind wandering should be significantly reduced. In actuality, mind wandering was extremely high, which to some extent supported the *Executive Failure Account* theory. And again, this theory did not explain why an individual with high working memory capacity faced a high frequency of mind wandering when engaged in the tasks with a low demand for cognition.

The Component Processes Account

In 2013, Smallwood proposed the "Process-Occurrence Framework," elaborating on previous theories of mind wandering from a new perspective. The "Process-Occurrence Framework" differentiated the initial reaction phase and continuation phase of mind wandering, linking the former with Executive Failure Account, and the latter with *Executive-Control Theory*. It was believed that mind wandering was caused by malfunction of the executive control system, and that its maintenance required cognitive control resources (Smallwood, 2013). Based on this framework, Smallwood and Schooler (2015) proposed the *Component Processes Account*, explaining mind wandering from three aspects. (1) The separation of cognition from external processing. This theory held that self-generated thought separated attention from extrinsic information, thereby increasing the processing of intrinsic information while reducing the processing of extrinsic inputs. (2) Task-unrelated thought arising spontaneously. Their study found that mind wandering contained episodic and effective processes. (3) Individual's regulation of the disengagement and self-generation processes. This theory showed that executive control processes and meta-cognition played important roles in the coordination of these two processes.

Deliberate/Spontaneous Mind Wandering and Creativity

In recent research, a new focus has been put on the distinction between intentional (or deliberate) mind wandering and unintentional (or spontaneous) mind wandering. Beghetto and Corazza (2019, p. 248) noted that: "The difference between these two kinds of MW stems from the mental dynamics underlying the onset of the experience of MW: whether the attentional shift (external-internal) occurs spontaneously or, somehow, under the individual's mental control. Specifically, in cases of deliberate MW, attention is intentionally shifted from the focal task to internal thoughts, whereas in case of spontaneous MW, task-unrelated thoughts capture one's attention, triggering an uncontrolled shift from the task at hand to other trains of thought."

Artists and creative writers usually tend to engage in intentional daydreaming, thus intentional mind wandering could be a characteristic of creative work. A recent study investigated the different contributions of spontaneous and deliberate mind wandering on divergent thinking and creative achievement (Agnoli et al., 2018). In this study, participants reported their everyday deliberate and spontaneous mind wandering using two 7-point Likert-type scales respectively. The results revealed that deliberate mind wandering positively predicted originality, whereas spontaneous mind wandering was negatively related to originality.

However, there is other evidence that supports the idea that spontaneous mind wandering might be related to creative thinking. A research study indicated that spontaneous mind wandering has a distinct relationship with ADHD (attention-deficit/hyperactivity disorder), where individuals with more symptoms associated with ADHD reported more spontaneous mind wandering than deliberate mind wandering (Seli et al., 2015). The researchers also found that adults with ADHD generate more original ideas on verbal creative tasks and have higher levels of real-world creative achievement. Therefore, it is possible that spontaneous mind wandering may play a role in creative ideation.

Why Does Mind Wandering Affect Creativity?

The above research provides both behavioral and neuroscientific evidence supporting the idea that mind wandering may facilitate creative problem solving. Despite that, the underlying mechanism of this relationship is not yet clear.

Several researchers suggest that mind wandering may amplify the incubation effect in creativity. One possible explanation is that mind wandering gives more room to unconscious processing. According to the Explicit-Implicit Interaction (EII) model of creative thinking (Helie and Sun, 2010), incubation involves unconscious and implicit associative processes that demand little attention capacity, rather than conscious, explicit, and rule-governed processes. This may in turn stimulate remote activation in semantic networks during an incubation period, and could thus improve later creative performance (Baird et al., 2012), as predicted by the spreading-activation account of incubation. At the neural level, a large amount of research has shown that mind wandering and creativity are both linked to the default network, incorporating the posterior cingulate cortex, the medial prefrontal cortex, the inferior parietal lobule, and the medial temporal lobes. Default network activation is most strongly associated with thought that is both task unrelated and stimulus independent, as mind wandering is commonly described. It was revealed that the default network plays a critical role in creativity, and researchers have temporally mapped brain activity during creative idea production and found default network activation during all stages of the task (Beatty et al., 2015).

On the other hand, the positive relationship between deliberate mind wandering and creativity suggests that controlling and monitoring processes are essential to creative thinking to some extent. Recent research has found that deliberate mind wandering is correlated with regions in both default mode and frontoparietal networks (Golchert et al., 2017). Mind wandering is now considered a dynamic mental state, with interactions of frontoparietal control, default mode, and salience network, which may be conducive to incubation. The dynamic state of mind wandering may minimize the costs of attentional lapses and improve creative performance (Leszczynski et al., 2017).

In addition, mind wandering is also related to an individual's personal goals and concerns, and contributes to planning and preparing for the future. Baird et al. (2011) tested whether mind wandering had a potential function of autobiographical planning. Their results revealed that the temporal focus of participants' thoughts was predominately future-focused when they were mind wandering, which means their mind wandering was primarily prospective. Furthermore, results found that goal-directed thought and self-related thought were more frequently future-focused than present-focused or past-focused. A meta-analysis study found that episodic future thinking and mind wandering have similar patterns of brain activation (Stawarczyk and D'Armentau, 2015). In addition, many neuroimaging studies have shown that the activation of the default network is associated with several other forms of self-generated thought besides mind wandering, including mental simulation, episodic memories, and future-focused thinking. At the same time, there is a lot of evidence suggesting that episodic future thinking has a positive effect on creativity. Thus, in this vein, episodic future thinking may be a possible explanation for why mind wandering has a positive impact on creativity.

Despite this evidence, several studies suggest that mind wandering during creative activities may actually impair the task performance (Hao et al., 2015). Creative idea generation is now recognized as a top-down control process, as the *Controlled-Attention theory* indicated (Beatty et al., 2014). Based on the *Executive-Control Theory*, if mind wandering consumed the control resources, it would drive individuals from current tasks and environments to their internal thinking, which would lead to performance deterioration by competing for executive resources. Creative ideation needs a large amount of control resources to maintain attention, and inhibit the interference of old ideas and external stimuli, so mind wandering was able to occupy the cognitive resources, and impair creative performance.

Introduction to Mindfulness

Mindfulness refers to “*the awareness that arises from paying attention in a particular way: on purpose, in the present moment, and non-judgmentally*” (Kabat-Zinn, 1994, p.4). This complex, multifaceted definition of mindfulness underlines three important attributes of mindfulness, which are the regulation of the focus of attention, the present (i.e., the “here and now”) as the focus of attention, and the attitude of openness and acceptance to the experience (Shapiro et al., 2006). According to Shapiro et al. (2006) the three components of mindfulness (intentionality, attention, and attitude) contribute to generate a “*fundamental shift in perspective*”: in the state of mindfulness, the individual engages in a clear observation of his or her moment-to-moment experience (e.g., thoughts, emotions, and bodily sensations), without reacting or judging it, with curiosity and nonattachment, being able to detach the contents of their thoughts and feeling from the self (“standing back” or “reperceiving” in Shapiro et al., 2006).

Mindfulness originally stems from Buddhist meditation traditions, which suggest that mindfulness as a state can be enhanced through an intentional regular practice of meditation (Lutz et al., 2007) and through structured mindfulness-based interventions (MBIs) that allow individuals to intentionally introduce mindful practices into their daily lives. Although there are different meditation practices (e.g., focused-attention meditation, open-monitoring meditation) and different MBIs (e.g., in clinical settings, mindfulness-based stress reduction (MBSR) program and mindfulness-based cognitive therapy (MBCT)), they all aim at helping people to “*become more aware of, and relate differently*” (Shapiro et al., 2006) to their experiences (including thoughts and feelings), instead of changing them.

Over the last two decades, mindfulness has become increasingly popular in the Western society receiving a great deal of attention in medicine, psychology, and neuroscience. This is illustrated by the dramatic rise in the number of studies on the effects of mindfulness meditation and structured MBIs on health and well-being, as well as on the cognitive changes resulting from practice of mindfulness meditation (Brown et al., 2015; see for a review, Tang et al., 2015). Globally, MBIs have been associated with a wealth of psychological benefits, ranging from a decrease of stress and distress and improvement of well-being and quality of life for people with chronic stress-related diseases, to improvement of symptoms specific of clinical disorders as depression, pain, anxiety, and addictive disorders (see for a review, Goldberg et al., 2018).

Neurocognitive studies on the effects of mindfulness meditation have also shown changes in multiple domains of mental functioning in both patients and healthy population: for example, mindfulness is reported to be associated with a better executive functioning (e.g., conflict monitoring) and selective attention abilities (e.g., orienting), with improvement in emotion regulation, decrease in emotional reactivity, intensity and frequency of negative affect, and increases in positive mood states (see for a review Tang et al., 2015).

Recently, neuroimaging studies have begun to investigate the functional and structural neural changes occurring in multiple brain regions in association with mindfulness meditation, raising the question of which underlying mechanisms support the positive impact of mindfulness on human psychological functioning. In this regard, as pointed out in a recent neurocognitive review on mindfulness meditation, “*there is emerging evidence that mindfulness meditation might cause neuroplastic changes in the structure and function of brain regions involved in regulation of attention, emotion and self-awareness*” (Tang et al., 2015, p. 222).

However, the question of “*how*” mindfulness works and the unique contribution of mindfulness compared to other interventions is still open and the interpretation of some results is made difficult by a number of methodological issues in the research area. One of the most relevant issues refers to the still relatively low number of longitudinal, randomized, and actively controlled research designs (i.e., designs with active interventions in control groups) in mindfulness studies. Some other issues are related to heterogeneity of interventions, in terms of practice duration and type of practice, as well as to the small sample size of participants.

Trait Mindfulness

As reviewed above, the majority of research on mindfulness has been focused on the investigation of the effects of mindfulness meditation and programs. However, another interesting contribution to our understanding of how mindfulness works has been recently provided by the empirical investigation of trait mindfulness (or dispositional mindfulness) which refers to the tendency to adopt a mindful perspective in daily life across situations and contexts. In this regard, several studies indicated that individuals strongly varied in their level of trait mindfulness, irrespective of mindfulness practice, although mindfulness meditation can enhance baseline dispositional mindfulness.

Understanding the relationship between trait mindfulness and psychological health and mental activity has important practical implications, for example, to shape individual-centered mindfulness interventions but to also promote mindfulness training as an intervention for those with low level of trait mindfulness (see Tomlinson et al., 2018). Research on this topic has been mainly conducted using self-report measures of mindfulness. Among the different instruments that vary in the breadth of mindfulness dimensions they assess, the two most commonly used are the Mindful Attention Awareness Scale (MAAS; Brown and Ryan, 2003) and the Five Facet Mindfulness Questionnaire (FFMQ; Baer et al., 2006). The MAAS is a unidimensional 15-item questionnaire, assessing the attentional aspect of trait mindfulness. The FFMQ is a 39-item questionnaire, derived from a factor analysis of five previously developed mindfulness measures designed to capture the diverse components of the multidimensional construct of mindfulness and to measure them separately. Specifically, FFMQ allows to assess five facets of mindfulness, namely the ability to observe and attend to different internal and external stimuli (Observing); the ability to focus attention with full awareness (Acting with Awareness); the ability to express experiences, thoughts, and emotions with words (Describing); the ability to not react to feelings, emotions, and thoughts (Nonreactivity); and the ability to not judge and rate thoughts, feelings, and emotions as good or bad (Not-judging).

Higher levels of trait mindfulness, as measured by MAAS, were found to be associated with higher levels of the personality traits of agreeableness (a tendency to be sympathetic and affectionate), and conscientiousness (a tendency to be thorough and deliberate), and with lower levels of neuroticism (e.g., Brown and Ryan, 2003). In line with the findings on the effects of mindfulness interventions on psychological health, trait mindfulness, as measured by MAAS, was also positively associated with measures of psychological well-being and negatively associated with depressive symptoms, anxiety, and eating pathology (see Tomlinson et al., 2018).

The adoption of a multidimensional approach in the assessment of trait mindfulness, using FFMQ, has recently contributed to further clarify the relationships between trait mindfulness and other psychological variables and to understand the hidden mechanisms by which mindfulness can lead to positive changes. For example, longitudinal studies have shown that not all components of trait mindfulness have the same influence on psychological health and suggest a substantial role of the “Not-judging” facet in the prediction of several mental health outcomes, particularly depressive symptoms (e.g., Barnes and Lynn, 2010).

In a similar vein, cross-sectional studies on the association between trait mindfulness and psychological well-being found that the two facets of mindfulness —“Acting with Awareness” and “Not-judging”— were positively related to well-being (e.g., Short et al., 2016). Moreover, comparisons between meditators and nonmeditators revealed different patterns of association between the “Observing” facet and measures of psychological health: in meditators the ability to notice and attend to internal and external experiences (i.e., “Observing”) was positively associated with adaptive characteristics (e.g., openness to experience and emotional intelligence), and negatively associated with maladaptive characteristics (e.g., alexithymia, thought suppression, rumination, worry, and dissociation), whereas in both healthy and clinical groups of nonmeditators, this dimension was modestly but positively correlated with several maladaptive constructs (e.g., thought suppression) (e.g., Baer et al., 2006) and it was a predictor of depressive symptoms (e.g., Barnes and Lynn, 2010).

Despite several methodological limitations of some of these studies (e.g., small sample size; lack of assessment of meditation practice; and heterogeneity of designs and measures), these results on trait mindfulness clearly show the importance of adopting a multi-dimensional perspective (which “aspects” of mindfulness are being examined) and also suggest that a specific mindfulness facet might work differently in a different “context”. In the case of “Observing”, a tendency to a close observation of internal and external experience may be adaptive or maladaptive depending on whether it is done with an accepting, nonjudging, and nonre-active modality. The adoption of a multidimensional approach seems to be very helpful also in understanding the complex association between mindfulness and creativity. This approach is, however, only one of the several approaches that can be found in the literature exploring the mindfulness–creativity link.

Mindfulness and Creativity

Over the last few years, increasing interest has been devoted to the investigation of the association between mindfulness and creativity. According to Langer, mindfulness is intrinsically inseparable from creativity because mindfulness requires the creation of new categories in order to organize awareness of the complex world (Moldoveanu and Langer, 2011). According to this approach, mindfulness is characterized by an active generation of categories or making distinctions, which are core elements in the emerging of novelty. Mindful people are situated in the present and directed toward the future, constantly aware of the ongoing situation. In the exact opposite of the mindfulness concept, this approach places mindlessness, a phenomenon that is instead overdetermined by the past. Given this intrinsic relationship between creativity and mindfulness, this approach exploits creative activities to increase

mindfulness. In this regard, evidence has been provided demonstrating that the creation of art, such as drawing an object, is able to initiate the mindful process as well as to increase mindfulness (e.g., [Grant et al., 2004](#)).

On the one hand, there are theoretical approaches that hardly distinguish between the two constructs; on the other hand, recent findings showed the relative independence of creativity and mindfulness. Hence, whereas convincing evidence for a relationship between creativity and mindfulness emerges from the literature, the nature and the strength of this association as well as the main psychological mechanisms defining this relationship are still unclear and debated.

Looking at the literature, two different approaches have been adopted in the study of this association. According to the first one, mindfulness is investigated as a unitary construct, resulting in a *uniform analysis* of its association with creativity. The second approach investigates mindfulness as a multidimensional construct, resulting in a *differential analysis* of the strength and directions of the associations between the (trait) mindfulness subcomponents and creativity. The following section will briefly describe these two approaches.

Uniform Analysis

Considering mindfulness as a unitary construct has proven to be particularly useful when the role of intervention (i.e., training) protocols is explored in association with convergent or divergent thinking. Within this approach, also the differences between expert meditators and novices are taken into account. Mindfulness is therefore considered as a complex practice that can affect a number of cognitive processes, including creative thinking.

Starting from a biological perspective, recent research explored whether the effect of mindfulness on creative thinking could be associated with an activation of the default mode network (DMN). DMN, also called “intrinsic network,” is a large-scale network including medial prefrontal cortex, inferior parietal lobule, posterior cingulate/precuneus, and the medial temporal lobe, which has been recently highly explored in association with creative thinking. DMN is related to intrinsically oriented functions and actions, such as autobiographical processes or planning future actions.

A recent study by [Berkovich-Ohana et al. \(2017\)](#) indicated that expert meditators in comparison to short-term mindfulness practitioners exhibited a greater fluency in a divergent thinking task and a concomitant reduced activation in DMN during a resting state. These findings seem to contrast with a series of consistent results showing an active involvement of DMN in creative behavior (e.g., [Beaty et al., 2018](#)), but they call for further studies in order to explore the association between large brain networks, mindfulness, and creativity. Exploring whether individual differences in trait mindfulness could act as moderator of the role of DMN over creative performance is in particular a topic for future research. Moreover, it would be particularly interesting to understand whether the inhibitory control exerted by expert meditators over DMN activity during a resting state, as emerged in the study by [Berkovich-Ohana et al. \(2017\)](#), has a direct impact on the intrinsically oriented functions (e.g., imagination) related to the generation of creative ideas.

In recent years, a series of studies explored the association of trait mindfulness and the impact of mindfulness training on convergent thinking, and specifically on the ability to solve insight problems. Insight problems are those in which the use of past experience or previous knowledge leads to an impasse that can be solved only through a full restructuring of the problem. In this regard it is worth highlighting that one of the aims of mindfulness meditation training is to reduce the role of past experience by decreasing the impact of habits on the way we act on and react to the world (i.e., generating the condition of a “beginner’s mind”).

Given this main characteristic of mindfulness, [Ostafin and Kassman \(2012\)](#) tested whether mindfulness might facilitate solving insight problems (comparing the performance in a series of insight and noninsight problems). The authors found that trait mindfulness predicted better insight but not noninsight problem-solving (which do not require the overcoming of habitual responses) and that mindfulness training could improve insight but not noninsight problem-solving. Similarly, [Greenberg et al. \(2012\)](#) evaluated cognitive rigidity in experienced mindfulness meditators and nonmeditators (Study 1) and in nonmeditators undergoing an 8-session meeting mindfulness program and a waiting list group (Study 2). The results of these studies showed that mindfulness could reduce cognitive rigidity leading to higher probability to find novel solutions to given problems. Again, the authors concluded that mindfulness reduces cognitive rigidity because it is able to induce a “beginner’s mind,” and immunizes individuals from being “blinded” to new solutions by past experience.

However, a more specific analysis on the strategies used to solve insight problems suggested that mindfulness can act differently on the diverse modalities used to solve insight problems. Two main routes have been identified as associated with the ability to find solutions to insight problems: insight and analytic problem-solving. Whereas insight is defined as the sudden realization of a novel solution or idea through the unaware spreading of activation in the semantic memory and the recombination of the existing information, the analytic strategy is related to the deliberate search for the solution which involves the aware control of the incremental progressions in the process through the conscious reasoning and the rejecting of wrong solutions.

[Zedelius and Schooler \(2015\)](#) demonstrated that individual differences in mindfulness (as measured by MAAS) have a different impact on the two problem-solving approaches, namely, insight and analytic problem-solving. Specifically, a greater tendency toward mindfulness increased problem-solving when problems were approached in an analytic way, whether this strategy was adopted spontaneously (Study 1) or instructed (Study 2). In contrast, a higher tendency toward mindfulness impaired problem-solving performance when problems were approached in an insightful way, whether spontaneously or through instructions. These results indicate that mindfulness impairs performance relying on intuitive thinking, while it enhances the performance that relies on aware control of the thinking process. The apparently contradictory results on problem-solving indicate that mindfulness does not

have a unitary beneficial effect on creative performance. These findings emphasize the necessity of a more complex approach highlighting some important distinctions in the relationship between mindfulness and insight.

Differential Analysis

In order to unravel the apparently complex relationship between creativity and mindfulness, a series of studies have taken into account the multifaceted nature of both constructs. Colzato et al. (2012) explored how different types of meditation techniques were associated with diverse creative thinking components. Specifically, the authors investigated the impact of focused-attention (FA) meditation and open-monitoring (OM) meditation, which represent two of the main techniques in Buddhist meditation, on convergent and divergent thinking. In FA the meditator focuses on a particular item or thought, actively ignoring everything else that can attract attention by redirecting attention back to the task focus. In OM meditation the meditator is free to observe or focus attention on everything she/he feels or thinks without a specific attention on a concept in the mind or a fixed item. The results of the study showed that practicing OM meditation (targeting the Observing component of mindfulness), but not FA meditation (targeting Acting with Awareness component), was beneficial for subsequent performance in a divergent thinking task (i.e., alternate uses task, AUT) but not in convergent thinking task (i.e., Remote Associates Task). The authors suggested that the benefits of OM meditation arise from a reduction in the degree of top-down control and local competition, thereby leading to a broader distribution of potential resources, which facilitates jumping from one thought to another—as required in divergent thinking tasks. More generally, these results highlight the theoretical impracticability in sustaining a unitary effect of mindfulness on creative behavior.

In a four-study work, Baas et al. (2014) directly tested the two competing approaches, namely, the uniform versus the differential impact of mindfulness on creativity (as assessed through divergent thinking tasks and self-assessment measures of creative attitudes and creative achievement). In these studies, mindfulness skills were measured (Study 1–4), extensively trained (Study 3), or manipulated with a short meditation session (Study 4). The results emerging from these studies supported the differential approach, clearly demonstrating that the association between mindfulness and creativity depends on the specific mindfulness component involved. In particular, this research showed that over the measured mindfulness skills only Observation was constantly able to predict enhanced creativity. Specifically, an increase of Observation induced through an 8-week mindfulness training was associated with increased creative tendencies. In addition, a manipulation of the Observation skill induced more original ideas in divergent thinking tasks.

Baas et al. (2014) demonstrated that this positive and strong link between Observation and creativity was partially mediated by the positive association between Observation and flexible thinking, a cognitive mechanism that past research already demonstrated to be an essential driver for creativity. Since flexibility only partially mediated the relationship between Observation and creativity, the authors proposed other explanatory mechanisms linking these two constructs. First of all, the authors proposed that openness to experience could put Observation and creativity in relation, since this trait strongly related to Observation and it is one of the most robust predictors of creativity. Moreover, since Observation is usually associated with the ability to efficiently recruit relevant information from the inner and the external world, creativity might benefit from this ability because of its strong dependence from the individual's skill to retrieve information from long-term memory and from the outside world. All in all, the results of this study confirmed the findings of Colzato et al. (2012), highlighting that Observation is the component of mindfulness that more strongly and consistently is associated with creativity.

Lebuda et al. (2015) carried out a meta-analysis on 20 studies (20 independent samples and 89 correlations obtained in a total sample of 1549 participants) exploring the relationship between the different mindfulness skills and different creativity measures. The analysis revealed that mindfulness and creativity are significantly related, with a small-to-medium effect size. As the author pointed out: "Although this effect was not moderated by the design of the studies, it tended to be stronger when creativity measurement had the form of insight tasks rather than divergent thinking tasks" (p. 24). The relationship was consistent across the different measures of mindfulness, but it resulted significantly lower when the mindfulness measurement method or the research aim were concerned only with the awareness dimension. This analysis confirmed past research showing that the relationship between creativity and this attention-based mindset (i.e., Awareness) is significantly weaker than in the case of other mindfulness dimensions. Interestingly, this meta-analysis registered no significant differences in the effects that emerged between correlational and experimental studies, showing not only that mindfulness and creativity correlate with each other but that enhancing mindfulness through meditation increases creativity as well. This result suggests that between mindfulness and creativity there is not only a correlational link, but also a causative effect. As the authors discussed, these findings have important consequences for the education of creativity, suggesting a beneficial effect of MBIs targeting specific mindfulness skills (e.g., intervention based on OM meditation).

Conclusion: Toward a Multidimensional Conceptualization of the Mindfulness–Creativity Link

Current research trends in the scientific literature are highlighting the need for a multidimensional approach in the study of both mindfulness and creativity. Approaching the study of these two constructs using a multifocal lens can allow one to disentangle the role of specific cognitive and attitudinal mechanisms over the creative thinking process, as well as to program *ad hoc* training interventions on specific mindfulness dimensions. It is clear that the multidimensional approach entails a higher level of complexity. This approach in particular leads to two orders of questions: (a) Since mindfulness does not happen in a *vacuum*, how does its

dimensions interact with other attitudinal/cognitive states in influencing creativity? In other words, since creative thinking is determined and associated with a *plethora* of individual differences (e.g., openness to experience, motivation, self-efficacy, etc.), research should pay particular attention to the interaction of the diverse mindfulness constituents with other individual differences and with the interfering role of other cognitive/emotional states and activities; (b) the second order of questions are related to the temporal dynamics in the interaction between mindfulness and creative thinking: Do the distinct mindfulness skills influence creative thinking differently depending on the stages defining this thinking process?

Evidence has emerged in the literature addressing these two types of questions. For instance, the interactive role of the tendency toward mindfulness and mind-wandering on creative performance (idea originality in a divergent thinking task) and creative achievement has been investigated in a recent study (Agnoli et al., 2018). Even if these two mental states have been traditionally intended as two antithetical constructs, their exploration in association with creativity has been addressed in this study using a multi-dimensional approach, distinguishing between the five mindfulness dimensions and between deliberate and spontaneous mind-wandering.

The results of this study highlighted that different mindfulness dimensions predicted creative performance and creative achievement both alone and in association with the two types of mind-wandering. These findings showed that mind-wandering and mindfulness are not mutually exclusive dimensions; rather, when explored as multidimensional constructs, they can interact in explaining the creative behavior.

This study showed that, when originality and creative achievement were jointly explored in a single statistical model as dependent variables, the Nonreactivity facet of mindfulness was negatively associated with the ability to produce original responses in a divergent thinking task, while the Describing facet predicted directly creative achievement. The ability to Nonreact to inner experiences emerged therefore to be detrimental for the production of original ideas. This finding could be related to the fact that Nonreacting to the emotional activation produced by internal feelings could block the beneficial effects brought by emotions in the production and selection of original ideas. The ability to Describe feelings and beliefs with words emerged instead as a direct predictor of creative achievement, showing that the ability to bring complex and original concepts from the internal to the external world is an essential skill to achieve creative success in real life. This result partially resembled the result by Baas et al. (2014), showing that the Description skills positively predicted increases in self-assessed creative behavior but not in creative performance. The direct effects of single mindfulness facets were combined in this study with interactions with the two mind-wandering dimensions. For instance, deliberate mind-wandering interacted with the Awareness facet of mindfulness in the prediction of originality. Specifically, high levels of originality were associated with high levels of deliberate mind-wandering, which interacted with the Awareness facet. According to the authors, this result might suggest that the ability to generate creative ideas is related both to a propensity to deliberately think beyond immediately relevant concepts and with a high tendency to reconnect with full awareness to the initial creative focus, which is needed to generate not only original but also effective ideas.

These findings highlighted the complex interactions between individual mindfulness attitudes and other personality or attitudinal differences. The multidimensional approach to the study of the mindfulness–creativity link was characterized by some inconsistency in results, in particular, on the role of the single mindfulness dimensions on creative performance. On the one hand, the different methodological approaches and research designs used in the literature to measure both mindfulness dimensions and creative performance should be taken into account. This could be a first source of confusion in the interpretation and comparison of the findings. On the other hand, it is worth highlighting that some results emerged as particularly consistent: the Observation facet emerged as especially important in relation to creativity, whereas the Accept with Judgment hardly emerged to be associated with the creative behavior.

Finally, interactive effects between the variables explored in the different studies should be considered when interpreting and comparing findings. A clear example of the importance of taking into consideration interactive effects are the results on the Awareness dimension emerged in the study by Agnoli et al. (2018): consistent with past research (see Lebudá et al., 2015) no direct effect of Awareness on creative behavior was shown in the study; however, this dimension emerged as particularly meaningful when explored in relation to mind-wandering tendencies. Future meta-analytic studies are therefore needed to measure interactive effects when analyzing the mindfulness–creativity link.

Lebudá et al. (2015) suggested that “It is likely that different aspects of mindfulness, such as open-monitoring abilities and awareness, play a role at different stages of the creative process” (p. 25). This reflection opens new degrees of complexity as well as new paths for future research. Not only could the different mindfulness dimensions have a different impact on creative thinking, but they could also impact the different stages of the creative thinking process in a different way. Most of the literature on the link between mindfulness and creative behavior has focused on the ideational state of the creative thinking process. It is worth highlighting that idea generation (i.e., ideation) is only a part of the multifaceted creative thinking process and a systematic exploration of the role of the mindfulness dimensions on different stages of the process has never been performed. Taking into account, for instance, Mumford’s model of the creative thinking process (Mumford et al., 1991), it would be fascinating exploring how the diverse mindfulness dimensions can influence the initial definition of the creative problem, the following information gathering and organization, the conceptual combination that precedes idea generation, the final idea evaluation/selection, as well as the idea implementation and monitoring. Mindfulness could indeed have a main importance in the establishment of initial motivational drives guiding the entire process as well as in the selection from memory, through inhibitory/excitatory mechanisms, of the information used to generate new ideas. By adopting such a perspective, it is clear that the research so far has explored only a drop in the ocean of the real possible areas of investigation of the mindfulness–creativity link. This realization sets a call for research actions

exploring the relationship between mindfulness and creativity, starting from the fundamental assumption of the multidimensional structure of the two explored constructs.

Introduction

Mindset is a collection of hypothesis, ideas, or assumptions held by an individual or group at a specific time. When these form an expectation towards a stimulus or problem, this is known as the Einstellung Effect.

This expectation can sometimes help problem solving and other times hinder it. Studies at the individual level focus mainly on the instances in which the Mindset is impeding the process of finding a solution (i.e., when the previous knowledge is no longer useful). In recent decades Mindset has also been studied as part of an executive function domain. There it is often referred to as the task-set that hinders the shift to solving a new task.

This entry will briefly describe a history of the terms. Then the Einstellung Effect will be discussed within the context of stimulus perception and as part of problem solving. The text will conclude with Mindset and Einstellung effect's relation to creativity and insight.

History of the Terms

Einstellung and Einstellung Effect are often traced back to Luchins' (1942) monograph. There "the habituation to the repeatedly used procedure [...] is [...] called an *Einstellung*" (p. 3, italicization in original). Furthermore, Luchins' paper defined "Einstellung problems" which may generate an 'Einstellung Effect' for the subsequent 'critical test problems', which, if the Einstellung operated, would be solved in the Einstellung method [...] and not in the more simple and direct fashion." In other words, the Einstellung Effect causes participants to solve problems in a potentially more difficult way as they repeat a previously learned solution.

These solutions can be trained through habituation. Luchins (1942) suggested a specific type of problems to test habituation: similar paths offer solutions to all problems with the subset of critical test problems offering additional and more straightforward solutions. Luchins' referred to Warren (1934) who described Einstellung as "the set which immediately predisposes an organism to one type of motor or conscious act." Later, Luchins (1942) gave more details by defining "Einstellung—habituation—as a mechanized state of mind, a blind attitude towards problems; one does not look at the problem on its own merits but is led by a mechanical application of a used method (p. 15)."

The context of Luchins' (1942) publication is interesting, as it ties closely to the Berlin School of Gestalt Psychology. Luchins referred to Norman Maier's work in mentioning 'some preliminary experiments' by Zener and Duncker with a similar setup. Abraham Luchins studied with Max Wertheimer in New York and became a close collaborator. Wertheimer himself was one of the founding fathers of Gestalt Psychology who fled to the USA from Nazi society in Germany. As one of the leading Gestalt Psychologists, Wertheimer was interested in effects such as insight as the moment of understanding the overarching Gestalt of a stimulus. In particular, he argued, only insight-based reasoning can solve conceptual problems. He expressed this in his seminal work 'Productive Thinking' and taught it at The New School in New York. Through his direct mentorship, Wertheimer's approach to problem-solving probably influenced Luchins work (see "Insight").

Further tracing the origin of Einstellung in another direction, Warren (1934) listed three possible interpretations of the term in his dictionary. The first is a predispositional 'set' towards a specific activity and shows great similarity with how Luchins used the term later. The second description shows a tendency towards a renewal of neural functions and references the work of Georg Elias Müller. The reference is to his work on 'psychophysics' and supposedly not Einstellung since Müller worked as an experimental psychologist in the 1870s. Finally, the third definition described readiness for monotonous work. While an explicit reference is missing, Warren's entry contrasts Einstellung as an unconscious process with 'Aufgabe' which he described as conscious and the cause of Einstellung. Therefore, this third interpretation is different from the contemporary understanding of the term. Interestingly, Warren (1934) listed another term 'determining tendency' as 'somewhat more specific than Einstellung' and suggested the work of Narziß Ach as a source for it.

Ach (1905) wrote about Einstellung more elaborately than ‘determining tendencies’ (orig.: ‘determinierende Tendenzen’). Specifically, he listed five different types of ‘sensory Einstellung’ (orig.: ‘sensorielle Einstellungsformen’) and additionally four ‘muscular Einstellung’ (orig.: ‘muskuläre Einstellungsformen,’ referring to the motoric system). Ach extracted these nine types of Einstellung from his experiments and observations. He discussed some of the forms and their relationship to observations by his colleagues.

In Ach’s text, written in German, the term Einstellung appears to be partially used as a technical term and partially as an everyday term. Furthermore, there are no explicit references to other publications to define Einstellung as a technical term. This missing reference suggests that Einstellung might have been a commonly used term in the circles around the developing Gestalt school in Würzburg and Berlin, as well as Wundt’s laboratory in Leipzig. In this case, the development of the term might have been a shared effort between the protagonists of early experimental psychology. Another interpretation would be that Ach (1905) was the source of Einstellung as a technical term, as he described each of the nine types in great detail.

In recent approaches, Bilalić et al. (2008) discussed Einstellung in the context of problem solving and equated it to the “negative impact of previous knowledge.” However, the relationship with problem solving is not that simple: The Einstellung can also have positive outcomes, and so-called “super experts” can easily overcome it.

Consider the other term of this entry, Mindset. There is no direct connection between the two terms, Einstellung and Mindset in Luchins’ (1942) work. Nonetheless, he mentions ‘set’ and references Gibson’s (1941) extensive publication on the history of ‘set.’ Gibson, however, who later went on to develop the theory of affordances, does not mention Mindset directly. Historically, he traces the term ‘set’ to the Würzburg Gestalt school use of Einstellung while admitting that the term has only been loosely defined. To illustrate this, Gibson listed 15 different types of sets, followed by 14 closely related terms – but Mindset is not one of them. Furthermore, he listed how often ‘set’ had been applied, among others, to different effects like the incubation process in reasoning, only partially seeing a problem and sensory hallucination. Gibson referred to Warren’s (1934) dictionary as another source, but there ‘set’ is described through synonyms like Einstellung and disposition, without explicitly mentioning Mindset. Gollwitzer, who used the term ‘mindset’ and ‘mind-set’ extensively in his publications, did not always provide an origin or definition for the term. Nevertheless, in one of his earlier publications, he seemed to use ‘mind-set’ as a direct translation of the term Einstellung (Gollwitzer 1990, p. 63). This is one of the earliest publications using Mindset as a technical term. Consequently, the term Mindset has only been used for roughly 30 years, while ‘set’ reaches back further, possibly even before Warren’s (1934) dictionary. Across all these publications, the terms ‘set’ and Mindset are consistently described as synonyms for Einstellung, for example as defined by Warren (1934): ‘set/mental = a condition of readiness for some specific type of mental performance — Ger. *Einstellung*’. Consequently, Einstellung and Mindset are two terms describing the same phenomenon. After the antecedent compilation tracing the historical origin of the terms, the following sections will describe research investigating the actual effects.

Mindset and Einstellung Effect in Problem Solving

To explore the Einstellung Effect, Luchins (1942) observed human problem-solving skills. In their experiments, Edith and Abraham Luchins asked participants to measure a certain amount of water. Three containers of defined size were given for each task with the goal to arrive at a specified amount of water at the end. For example, if given a 29 and a 3 unit sized jar, to arrive at 20, participants could solve the problem by scooping the smaller jar three times from the filled bigger one.

The experiment started with moving water between jars to demonstrate the task. This demonstration was followed by five tasks which could all be solved similarly. Namely, the solution required to move water from the first jar to second and then subtracting two more of the third jar from it. Representing the jars through A-C and the solution by S, the solution to the first five tasks was $B - A - 2C = S$. These tasks were followed by four more, which could be solved in the same way, or by doing just a simple step of either adding or removing water once. While the solution $B - A - 2C = S$ would still work, the more straightforward solution would equate to $A + C = S$ or $A - C = S$ and require participants to start with another jar than B.

The majority of participants who engaged in the first five tasks did not change to a more straightforward solution. Instead, they solved the remaining problems by starting with B. Participants who only saw the latter problems, were able to solve them, starting with A, which shows it is not a matter of task difficulty. These results showed that participants tended to use the same strategy they applied to previous tasks for the final four tasks as well. Presumably, they ‘set their mind’ to a particular strategy and learned a specific solution throughout the performance of the tasks. As a result, they had formed some expectation toward the nature of the problem and how it could be solved. Since the longer path still leads to a solution, the Mindset from the first tasks was kept intact.

The Einstellung effect has had negative connotations since the initial description, such as ‘blind attitude towards problems’ and Luchins (1942) elaboration on the negative emotions that his participants conveyed through their comments. Furthermore, and contrasting it with the *Sequence effect* coined by Hull in the 1920s, the Einstellung effect has since been described as the negative aspect of transferring knowledge (cf. Sweller, 1980). Conversely, a certain Mindset and hence the ‘habituation to the repeatedly used procedure’ allows quick and effortless problem solving when ‘surface features’ and ‘abstract solution structures’ remain the same across tasks. In this case, participants benefit from the sequence effect by applying previously learned solution paths to similar or analogous problems. Already Luchins (1942, p. 93) mentioned the positive aspect of speedy responses to recurring situations and suggested, that this would ‘free the mind [...] to ...] deal with complicated tasks’.

On a functional level, finding the solution is then more of a memory recall than investing energy into finding a novel solution to a problem. On the other hand, if the ‘surface features’ remain similar while the underlying ‘abstract solution structure’ has changed, applying the same solution path can have two possible outcomes. Firstly, if the previously learned path does not yield a solution, this might trigger a new problem solving process, possibly involving an impasse due to similar surface features. Secondly, if the problem can be solved using the same solution path despite a possibly easier solution, this is referred to as the Einstellung effect.

Referring back to the water jar problem and framing it as an optimization problem, shortening the solution path by two water movements might look like a notable improvement. Consequently, and mediated through the Einstellung effect, ignoring the shorter solution appears like a waste of resources, especially considering theories along the lines of the free-energy principle. However, keep in mind that Luchins (1942) administered the tasks as a pen-and-paper experiment. The difference in time and energy investment between executing a four-step solution and a one-step solution was minimal for the participants. Hence, recalling a working and known solution was arguably the faster and more energy-efficient solution. The results by Vallée-Tourangeau et al. (2011), who asked participants to move water in addition to the pen-and-paper solutions, support this argument.

From the initial experiments on, Mindset can be observed in the context of learning as well. Participants in the Luchins experiment learned how to solve a specific type of problem and once learned it was easier and arguably more energy efficient for them to apply the process to seemingly similar problems. In a sense, these participants who repeated a previously learned experience reacted less to a particular and novel stimulus, but rather to their representation of seemingly similar problems. The clinical conditions of perseveration, for example, described by Sandson and Albert (1984), take this to the extreme. Here specific behavior and reactions were initially learned or triggered by stimuli, yet in the case of diagnosed perseveration, the absence of stimuli produced the same behaviors. Sandson and Albert (1984, p. 715) summarised previously published classifications, and suggested that these stuck-in-set perseverations are based on an ‘underlying process deficit in executive functioning.’ Having these extreme forms of Mindset linked to neuroanatomical features and deficits, one could argue that even perception is related to the Einstellung effect.

Whenever the set refers to a known function of a particular object that interferes with finding alternative uses of that object, this phenomenon is called functional fixedness (Adamson & Taylor, 1954). This effect is consistent across older children (from 6 years on), and adults too (Defeyter and German, 2003), but younger children before their fifth year do not exhibit this behavior. These findings imply that younger children do not yet know the functions of objects well and as such, they allow any intentional use to be an object’s function. Looking at all age groups, some argue that having the knowledge about objects functions impedes problem solving (i.e., leads to functional fixedness), others found that knowledge helps (Bilalic et al., 2008; Munoz-Rubke et al., 2018). For example, in the context of chess, Bilalic et al. (2008) found that up to a certain level of expertise the Einstellung effect is easily observed, but “super experts” are better in overcoming the functional fixedness of a known position and are more likely to find novel solutions. Thomas et al. (2018) demonstrated another example of the link between knowledge and Einstellung: For a magic trick, participants received a description of how the legerdemain worked. Nevertheless, this information seemed to trigger an Einstellung effect and fixated them on the wrong solution (see “Magic”). These two examples illustrate that the link between the knowledge base and the Einstellung effect are not well understood and possibly extend to other factors.

Einstellung also plays a vital role in research on executive function and attention. In this area, ‘set-shifting’ as one important executive function (Best et al., 2009) is explicitly linked to Mindset: The ability to shift, or to break the set, refers to the ability to change the rule or the task when solving a problem. In other words, the ability to shift attention efficiently reduces the Einstellung effect and results in not perseverating in the initial rule or task. Studied mainly with the task-switching paradigm, a plethora of studies showed that there is a switch cost immediately after a task switch, proving that the formation of a set does interfere with current problem solving. As such, attention shifting may be one core-specific mechanism that is involved when one needs to overcome the Einstellung or Mindset effect.

This section discussed Mindset in terms of higher-order cognition. The following section will explore how visual and auditory stimuli are perceived differently based on inner states by relating the Einstellung Effect to a range of perceptual tasks.

Mindset and Einstellung Effect in Perception

In addition to higher-order cognitive tasks and problem solving, other perceptual tasks expose characteristics of Mindset and the effect of Einstellung. This examination applies to the literal interpretation of Einstellung as an attitude towards a stimulus, as well as the definition developed following Luchins’s work. Notably, the mechanized states of mind towards visual and auditory stimuli influence how they are perceived. This entry puts forth the argument that the Mindset drives the understanding of a stimulus. This insight follows the general trajectory of cognition influencing perception ‘top-down.’ Einstellung has also been argued to have neural plasticity effects and would consequently have a long-term influence on bottom-up processing. As the Einstellung effect is often referred to as a short-time intervention, this section focuses on the top-down processes.

In their overview of top-down processes, Scocchia et al. (2014) discussed how visual stimuli and the visual system can be influenced using the example of multistable stimuli. In particular, the discussion on voluntary control and perceptual dominance relate to the Einstellung effect: Voluntary control describes the ability of people to influence the duration of holding a single interpretation of a multistable stimulus or influence the frequency of switching between different percepts. This voluntary switching behavior is known for the modality of visual perception as well as for auditory stimuli.

For the example of visual stimuli, Scocchia et al. (2014) referred to a rich history of experiments dating back as far as Helmholtz’ experiments in the 1850s where participants were instructed to hold one possible interpretation as long as possible or switch

between percepts. This top-down control on the perception in the visual system showed the influence of the participants' Mindset on perception. Another example of a Mindset for these stimuli utilizes perceptual dominance. [Scocchia et al. \(2014\)](#) discussed how the sequential presentation of stimuli resulted in the adaptation of the dominance of a specific interpretation. Further support for the influence of Einstellung on the perception comes from experiments where bistable stimuli are interleaved with blank periods, where the frequency of switching is slowed down significantly. [Scocchia et al.](#) explained this observation through the "dependency of current ambiguous perception from prior history of perceptual dominance" (p. 10), which seemingly refers to the mechanized state of mind derived from the likes of Luchin's definition of Einstellung.

For both cases, voluntary control and experiments relying on perceptual dominance, the viewer generates a switch between perceptions that is not visible in the stimulus itself. This relates to the extensive collection of visual illusions such as the Kanizsa triangle, where fragments of black circles with cut out slices create the illusion of a bright white triangle. Historically, the proponents of Gestalt psychology have collected illusions, where the people's prior knowledge and the arrangement of stimuli facilitate the perception.

This section referred to the Einstellung effect in the context of top-down influences, which was critically discussed, for example, by [Firestone and Scholl \(2015\)](#). Their claim 'cognition does not affect perception' seems to conflict with the arguments presented so far. However, even these critical readings of the literature acknowledge that attention, memory, and response biases influence the reaction to stimuli. Specifically, their conclusion appears to relate to the question at what level higher-order processes influence a reaction to stimuli. For the discussion of Mindset within this entry, the exact influence of higher-order functions on perception is irrelevant. That is, as long as there is any influence. Therefore, this particular argument by [Firestone and Scholl \(2015\)](#), along with the discussion in the open commentaries supports the existence of an Einstellung effect on perception.

The Relationship to Creativity and Insight

The seminal article by [Luchins \(1942\)](#) opened – as discussed earlier – with a reference work on insight in problem solving. In insight, the solution of the problem comes spontaneously in conscious thought, and often this requires going beyond known solutions. Because learned solutions form the Mindset, they can interfere with new solutions when the older ones instill a mental rut. Insight seems to be substantially involved in creative thought, with the latter being fundamental for innovation. The relationship between Mindset and insight is frequently presented to be negative: When the Mindset leads to a perseverative exploration of known paths for solving the problem (i.e., the Mindset is highly probable), insight cannot manifest itself (i.e., is less probable to occur). One explanation for this type of relationship may be the fact that while insight is based on restructuring both previous knowledge and the problem information, Mindset and more specifically the Einstellung effect usually implies going along known paths. Furthermore, the Mindset seems to block the way for originality, an essential requirement of creative thinking. As such, there is agreement that Mindset leads to rigidity of thought ([Schultz and Searleman, 2002](#)).

Recent results showed that successfully solving insight problems does not depend on the initial problem representation but on controlled processes of reasoning. Namely, the process of surpassing the Mindset by suddenly arriving at another viable solution seems not to be well understood so far and may be just another case of carefully but implicitly controlled reasoning. Just like for creativity where both convergent and divergent thinking are needed, studies investigating insight show that processes involved in the emergence of sudden AHA moments are very complex ([Rothmaler et al., 2017](#)).

Assuming creativity could be understood along the dimensions of usefulness and novelty, another discussion suggests itself. As discussed earlier and highlighted throughout the literature, Einstellung is useful and leads to useful behavior. Therefore, if Mindset is about the habituation of an attitude towards a stimulus, the Einstellung effect leads to anything but original behavior. Moreover, even if alternative solutions become easier, people with a certain Einstellung 'stubbornly' stick with their previously habituated solution path. Arguing from the experimenter's point of view, this defeats the definition of novelty. Instead, if taking a stance from the task's point of view, there are two different types: One task with only a single solution, and the other type with two solutions. The two solutions seem to exhibit different difficulties, as Luchins demonstrated through the control trial. The result of the experiment showed that people in the Einstellung condition chose to solve the second type of problems through their more difficult and less obvious solution. Taken by itself, this behavior could be considered original as it diverges from the normal behavior. In fact, in divergent thinking tasks answers are often scored independently from each other while the stimuli, as well as the narrative of the previously given answers, could result in a bias leading to more original solutions. Consider, for example, a participant who starts thinking about using a brick for artistic purposes, maybe for a modern architectural building, a statue, and an art installation. In this case and by transferring a context from one idea to another, the Mindset could lead to the highly original solution of grinding the brick to use its pigments as paint.

An extension of this idea of Einstellung as a mediator of knowledge between domains into real-world applications could be the contribution of researchers in interdisciplinary collaborations. While biased towards a particular set of tools, knowledge, and the underlying philosophy, the combination of Einstellung from each contributor leads to novel approaches that diverge from habituated solution paths. Further considering the similarity between Einstellung and biases, this would even have implications for science itself and the underlying philosophies ([Andersen et al., 2019](#)). Drawing together these two examples from divergent thinking tasks and interdisciplinary team science, the interaction between Einstellung and creativity are apparent. While it would be too superficial to consider Einstellung as an enabler for creativity, there is more to the relationship than meets the eye (see "Interdisciplinary Approaches to Creativity").

Final Thought

Is Einstellung a general effect for humans? Even if the cognitive set is implicitly considered to be specific to humankind, recent work suggests that culture and schooling have an influence. For instance, Pope et al. (2019) found that semi-nomadic Himba people are not affected by cognitive set in the same way as Western participants. Interestingly, Himba participants chose the novel shortcut more often than Westerners in a computerized ‘Learned Strategy — Direct Strategy’ task. Pope and her colleagues explained the results in terms of environmental uncertainty and educational background. Namely, they suggested that the environment of Himba people poses higher levels of uncertainty. Pope et al. (2019) also pointed out that the Himba education puts less emphasis on repetitions than western societies do in their school systems (see “Education and Creativity”). Thus, the question of Einstellung as a generalized phenomenon arises and asks for future clarifications.

The Nature of Morals

In this chapter morals will be understood in the sense of normative ethics: a framework for working out which actions are virtuous and which are wicked (e.g., good as against bad, righteous as against unrighteous, or worthy of emulation as against unworthy). Creativity will be understood in the now familiar sense of production of relevant and effective novelty. The key questions underlying the chapter are: Can creativity be judged according to moral precepts? What makes creativity moral and when is it immoral? How can moral creativity be promoted?

Moral precepts are not physical laws or forces of nature, but are ideals that have been worked out by philosophers, religious authorities or other thinkers, although they may have demonstrated their worth in people's practical experience of life (as the evolutionary view of morals mentioned below particularly emphasizes). Morals are a matter of subjective internal conviction rather than concrete evidence or physical or even legal coercion. They often reflect the influence of religion or philosophy, culture, family and friends. Although there is obviously a connection between them, morality and law are not the same thing. Some actions are legal, but of dubious morality. On the other hand, some actions are illegal, but are regarded by many people as moral. Although moral transgressions may be punished by condemnation, rejection, public humiliation, or other external sanctions, they are also strongly enforced by internal sanctions such as pangs of conscience or feelings of shame. The truly moral person behaves in a moral way out of personal conviction.

Moral Behavior

A sister topic to morals is ethics: Ethics are concerned with how a moral person should behave. Ethical behavior involves doing what is morally right and proper, and not simply what is expedient. According to Marc Bekoff and Jessica Pierce, morals involve 'a suite of interrelated other-regarding behaviors that cultivate and regulate complex interactions within social groups.' This definition directs attention squarely to the social nature of morals and in particular to the central role of concern for the well-being of others (morals are other-regarding). Immanuel Kant argued that there is a 'moral imperative' to treat other people with dignity, and never to exploit them as instruments of one's own satisfaction. According to John Locke, no-one should act in such a way as to harm anyone else's life, health, liberty or possessions. For Locke, these were natural rights, given by God. Unfortunately, despite Locke's attribution of moral principles to God, people's ideas of what is right and proper are highly subjective, and often differ sharply from person to person, from society to society, and, indeed, from era to era; Galileo's publication of his (factually correct) thesis that the earth rotates around the sun (and not vice versa) was regarded in his own time as so morally reprehensible as to constitute heresy, and led to years of house arrest. Thus, being factually correct does not guarantee acceptance as morally or ethically good, especially where the facts contradict pre-existing fixed beliefs, as was the case with Galileo.

Nonetheless, some ethical values transcend cultural, religious, or ethnic differences, and thus involve something approaching a universal moral worldview. According to Plato, for instance, there are four 'cardinal' virtues (courage, temperance, prudence, and justice) which should guide all actions. All other virtues are thought to spring from these. Examples of widely accepted virtues

☆ *Change History:* August 2019. Arthur Cropley updated the text throughout the article.

This article is an update of A.J. Cropley, Moral Issues in Creativity, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 140–146.

are responsibility, fairness, concern about the well-being of others, good citizenship, integrity, sincerity, trustworthiness, generosity, and fortitude, all of which are mentioned by numerous writers in the area. Such writings are not confined to the Western, Aristotelian tradition. The Confucian construct of 'ren' is an example of a broad definition of what is right and good that is widely accepted in Asian countries and beyond. Ren can be translated as 'righteousness.' It includes moral virtues such as loyalty, consideration, conscientiousness, or altruism.

Morality and Creativity

When applied to creativity, questions of morality are initially centered on whether creativity can be judged in moral terms at all. Despite the conclusion of some writers such as Mark Runco that creativity or creative thinking processes are neither moral nor immoral in themselves, or even that creativity is above such considerations, Robert McLaren pointed out that creativity has come to have a 'quasi-religious function' in modern life, according to which it is widely regarded as the epitome of goodness. This spiritual tone was already present at the beginning of the modern creativity era: Jerome Bruner saw creativity as the last bastion of the admirable side of the human spirit in an age in which electronic devices are taking over many functions. Nowadays, creativity is frequently proposed as the human counter-thrust to the recent rise of cyber-physical systems in the sense of Industry 4.0, which really are beyond considerations of good and evil.

Discussions along these lines have not infrequently argued that creativity is a primal force of nature, and that it is, by definition, a universal beneficial factor fostering growth and rebuilding in all organic systems, and is thus automatically good. Brian Henning referred to it as 'the dynamic process of the universe.' According to Friedrich Nietzsche in his discussions of art and music and their relationship to aesthetics and ethics, they involve 'deification of existence.' In fact, research has shown that, almost without exception, the term creativity itself and all synonyms for it are still almost always used in a positive sense in modern psychological discussions.

Immoral Creativity

However, it is difficult to regard, for instance, the effectively novel systems for killing people in large numbers generated by Hitler or Stalin or the undoubtedly novel attack on the World Trade Center in 2001 as the same in principle as the works of, let us say, Shakespeare or Mozart. It is conceivable that the cognitive processes are similar in all four cases (for instance, generation of alternative ways of seeing things, linking of ideas usually kept separate, or branching out from the known in a new direction). However, apart from the differences in the nature of the products—works of art vs. technological and management systems—there is a clear difference in the products of the creativity of Hitler and Stalin vs. Shakespeare and Mozart; on the one hand, death and destruction for people not actively engaged in any directly hostile activity, on the other, things of beauty. Furthermore, and of central importance for this chapter, there were substantial difference in the intentions of the persons involved: on the one hand a desire to generate truth and beauty, on the other, a desire to do harm and wreak destruction for essentially political purposes. Paraphrasing Darcia Narvaez and Kellen Mrkva, moral creativity requires not only the ability to generate useful novel ideas, but also the ability to form ideas about what is good and right (and to do good).

The problems associated with morality in creativity are, to some degree at least, inherent in creativity itself. The essence of creativity is changing what currently exists. Among other things it:

- shakes the foundations of the received order and brings uncertainty for other people,
- questions the value of existing knowledge and skills (often laboriously acquired),
- threatens loss of status and authority for experts, leaders, or established creators,
- encourages dissatisfaction with the status quo, restlessness or rebellion,
- encourages putting your own needs and resolving your own dissatisfaction ahead of the needs of others.
- opens the door to dark and destructive material that needs to be handled with great caution (see below).

These processes can easily become destructive, especially if they are self-centered and self-serving, or are applied recklessly. They yield moral results only when they promote fairness, justice, good citizenship, altruism, and the like, rather than furthering the narrow self-interest of an individual or a special group. Thus, the seeds of immorality are inherent in the very nature of creativity.

Negative effects of creativity need not arise from deliberate malevolence. Some negative effects are very difficult or impossible to anticipate: the lifesaving discoveries of Louis Pasteur and Edward Jenner, for instance, laid the foundation for germ warfare. Some people may even create obviously immoral products despite generally having positive moral values and wishing to behave in an ethical manner. They may, for instance, consciously or sub-consciously blind themselves to the immoral consequences of their work, be unable to or unwilling to anticipate negative consequences, or succumb to temptation. This may occur, for instance because of their fascination with what they are doing, or because they are deceived or coerced by factors like the prospect of money and fame or the manipulation of a despotic government. Maria Zaitseva gives the example of how this happened with some participants in the Soviet Union's program for the development of weapons of mass destruction, while David Hecht made a similar analysis of the role of American nuclear scientists in the US atomic bomb program late in World War II.

A related moral issue in connection with creativity is described by Kevin Hilton. One person's acclaimed and highly respected artistic/aesthetic creativity may inspire another person's antisocial behavior, despite the absence of any negative intention on the

part of the creative individual. An obvious example is the copying of evil deeds depicted in imaginative works. Hilton gives the examples of a murder committed using a technique described in the novel *Shibumi*, and a double murder committed by copying a scene in a Clint Eastwood film. Another example is the 'Werther effect': A wave of suicides inspired by Goethe's book, 'The sorrows of young Werther,' caused the book to be banned in several countries. An artistic creation that is successful in informing, entertaining, even inspiring readers, listeners, or beholders (which seems moral enough), may simultaneously encourage, promote or provide models of behavior which should not be emulated. Perversely, it even seems that in such situations greater creativity may be more likely to promote antisocial behavior: the greater the creativity, the worse the negative effect.

One of the potentially destructive aspects of creativity is that it involves dissatisfaction with what already exists and an inability or unwillingness to accept the status quo. Albert Einstein reported how his recognition that existing theories of electrodynamics were inadequate motivated him to develop the special theory of relativity and then the general theory. Einstein continued to be dissatisfied with his own theory, and worked on it for much of the rest of his life. America's most distinguished inventor, Thomas Alva Edison, was never satisfied with his own inventions, and over the years took out more than 100 patents on the electric light bulb alone. Michael Mumford and Peter Moertl described two case studies of innovation in social systems (management practice and student selection for admission to university), and concluded that both innovations were driven by 'intense dissatisfaction' with the status quo. Thus, seeing that something is wrong with existing knowledge, criticizing this knowledge and seeking to overthrow it are core elements of the creative process. These can be very threatening for people around the creative individual.

Focusing on artistic and aesthetic creativity, Liane Gabora and Nancy Holmes gave examples of its destructive effects on creative people themselves, listing numerous 20th century poets, writers, musicians, and painters who committed suicide. They also reviewed discussions of the question of whether creativity causes psychological disturbance or psychological disturbance leads to creativity. They referred to the 'shadowy swamplands of the creative mind,' and suggested that creativity may lead people to delve into destructive elements of the unconscious in a process of 'deep mining into the darkness,' sometimes bringing to the surface material that less-creative people—wisely—leave undisturbed. They suggest that precisely this process of going where others fear to go may lead to an 'allure of darkness' that makes this side of creativity attractive to some creative individuals as well as to some of the people who admire their work, sometimes with ultimately destructive results. Is such creativity moral, or immoral, even if it yields works of great artistic merit?

Moral Creativity

Despite what has just been said, in a certain sense creativity really is inherently good: As [Jasper \(2010\)](#) pointed out, relevant and effective novelty (creativity) always brings benefits of some kind to someone (otherwise it would not be relevant and effective). The problem is thus not the presence or absence of benefits deriving from creativity, but the distribution of the benefits and the kind of benefit. If the advantages flow in one direction and the disadvantages flow in another, then the creativity is positive for one side, but negative for the other. If the disadvantages to the losing side are of an unjust or undeserved nature or extent (morally indefensible), then the creativity has an immoral aspect. To take a simple example: the invention of the steam engine produced enormous benefits for society, but spelled ruin for highway robbers. However, most people would probably agree that in this case the harm the creativity caused to highwaymen could be ignored (or even welcomed), because such harm was just and deserved.

The Relativity of Benefit

The crucial question is for whom the benefits flow; what David and Arthur Cropley call 'relative' benevolence. [Robert Sternberg \(2010, p. 318\)](#) extended this two-dimensional approach (benefit versus harm) by discussing three dimensions: intra-personal benefit (benefit for one person only or a small in-group), inter-personal benefit (benefit for other people as well as the person generating the effective novelty), and extra-personal benefit (benefit for the context or setting such as a firm or country, humankind or the environment). These three dimensions help to make the difference between moral and immoral creativity clearer. Creativity that provides extra-personal benefits has good prospects of being moral, whereas creativity that involves only intra-personal benefits can easily lead to harm for others. Even though worldwide drug dealing, human trafficking, or terrorist disruption of normal life may generate strikingly effective novelty and bring great benefit to the perpetrators, at the extra-personal level there are many losers, and the creativity involved is clearly immoral.

The idea that moral creativity can be defined in such a straightforward and yet broad and sweeping way as generation of effective novelty that promotes the common good may seem excessively simplistic. However, it is consistent with the views of philosophers who have wrestled with the issues at stake. Immanuel Kant defined creativity as 'the aspiration to create a perfect world for everyone.' He also defined creative genius in terms of producing ideas that are both original and exemplary. By 'exemplary' he was referring to the categorical imperative to fulfil all moral duties. Brian Henning worked out a number of obligations for moral creativity from the writings of Alfred North Whitehead: The obligations include beauty (to bring about the widest possible universe of beauty), love (to maximize the intensity and harmony of oneself and everything within one's sphere of influence), and peace (to avoid destruction). All of these obligations involve a responsibility to avoid doing harm to others and to promote the common good of the larger society.

Recognition of the link between moral creativity and furthering the well-being of other human beings is not new and is not confined to the western world. The Chinese Emperor, Han Wudi, who reigned until 86BCE, was intensely interested in finding

innovative thinkers and giving them high rank in the civil service, and reformed the method of selection of mandarins to achieve this. Writing in the 17th century, both Francis Bacon and René Descartes, two of the founders of modern science, saw creativity as involving the harnessing of the forces of nature for the betterment of the human condition (i.e., for moral purposes). Among Indigenous Australians and the Maori people of New Zealand, First Nations in Canada and Native Americans, creativity implies benefiting other members of the community.

Morality and Intention

The most obvious examples of creativity of questionable morality are to be seen in the generation of novel products that harm people or, as is increasingly emphasized nowadays, the environment. This involves what Keith James called 'negative' creativity. The harm to others can be simply a collateral effect; an employee who devises a novel and highly effective way of avoiding work may expose other people to the stresses of overwork, but this is not the primary intent of the negative creativity. More obviously immoral is creativity which has the deliberate and planned primary intention of harming others, referred to by David Cropley, James Kaufman and Arthur Cropley as involving 'malevolent' creativity. A gray area is to be seen in the field of crime. As Lorraine Gamman and Maziar Raein pointed out, 'resourceful offenders' constitute a group '... whose creativity is rarely acknowledged.' According to these authors, some '... criminal "projects" may exhibit the "wow" factor, and even represent paradigm-breaking creative breakthroughs. For this reason, observers are tempted to admire such projects, even though their intention is anti-social.

Thus, at least two factors contribute to the morality of creativity. The first involves the product or outcome of the effective novelty and especially the question of relative benefit. The second is the intent of the individual, or possibly the organisation, generating it. Without the intention of causing harm, creativity is not malevolent, even when its results are harmful or undesirable. It seems certain that Karl Benz, who designed and built the first four-stroke engine, did not do so with the deliberate intention of polluting the environment or killing people, so that, despite its massive death toll, his engineering creativity was not immoral. On the other hand, the 9/11 terrorists set out to create a novel form of attack on their opponents with the deliberate intention of causing the deaths of many people and the widespread destruction of property.

Introducing the concept of harmful intent expands the morality of creativity from two categories (positive—negative) to four (deliberately good, deliberately bad, unintentionally bad and—difficult to imagine in practice, but theoretically possible—unintentionally good). This categorisation makes it possible to turn attention from the products of creativity alone to the motivation of the person or persons generating the novelty. Runco (1993) referred to the four 'quadrants' and Cropley (2010, p. 367) named the quadrants 'consciously benevolent creativity,' 'failed benevolent creativity,' 'consciously malevolent creativity,' and 'failed malevolent creativity.' Only the latter two are immoral, despite the possible bad outcome of failed benevolence and the possible harmless outcome of failed malevolence.

The Role of Wisdom in Moral Creativity

Kevin Hilton saw a need for 'social wisdom' in creativity. This is based on a 'multi-perspective community approach,' and relates the effects of creativity to its social context. To promote understanding of the relationship of creativity to the social context, Hilton called for emphasis on 'the hard-won insights of the past,' thus incorporating the historical context and the accumulated wisdom of previous generations into the understanding of morality in creativity. Robert Sternberg, too, identified the crucial factor in moral creativity as 'wisdom.' He sees wisdom as involving awareness of the need to balance personal interests and the general good, willingness to do this, and the ability to do so—to find a compromise path that satisfies both sets of interests. The central characteristic of wisdom—as against, for instance, intelligence—is concern for the common good: A wise person tries to contribute to the common good, not to pursue solely his or her own advantage, and moral creativity seeks to generate effective novelty in order to promote the common good.

From an American point of view, the 9/11 attack did not display wisdom, since its intention was not to serve the common good, so that, despite its surprisingness and effectiveness, it was immoral. Nonetheless, it may well have seemed to the attackers—rightly or wrongly—to be advancing the common good of some other ethnic or national group(s), so that even wisdom is relative. In times of war this issue becomes particularly acute. People who generate effectively novel devices with the sole purpose of inflicting damage and death are frequently judged to be acting in a moral way by one side in the conflict, even though it is clear that they understand the 'common' good in a relatively narrow way.

How Do People Become Moral?

Moral creativity can bring great benefit for human beings and their environment, but immoral creativity can bring great harm, as was discussed above. It seems to be a matter of public interest that creative people possess positive moral values and apply them to their own behavior. How does this occur? Evolutionary biologists and socio-biologists believe that morality develops as a result of evolutionary forces. Seeking justice, fostering the well-being of others, showing courage, co-operating with others, and similar behaviors are not the only behaviors of which people are capable. Unfairness, lack of concern about others, avoiding danger, and exaggerated individualism are also possible (and indeed, are not especially uncommon in real life). The widely-accepted morality outlined above is thus not absolute, but relative, and in theory any set of values could be adopted. However, properties such as justice,

concern about the well-being of others, co-operation and courage enhance the survival both of the individuals who display them and also of the collective to which the individuals belong. As a result, such moral values have come to prevail through the process of natural selection. Indeed, according to biologists, simple versions of what humans regard as morality are seen in all species.

In psychological thinking, however, the acquisition of moral values is mainly regarded nowadays as the result of learning from other people. According to the psychoanalytic view, morals are imposed upon the developing child by its parents, and are resident in the super-ego, from where they may cause neurotic symptoms in the individual when they conflict with innate drives that are oriented towards the satisfaction of individual, self-centered urges, possibly at the expense of the collective. However, the most influential modern description of the psychological process of moral development is that of Lawrence Kohlberg. He proposed that children acquire understandings of concepts such as justice, equality and concern about the welfare of others as they move through a series of six developmental stages. At the lowest level, young children define right and wrong in terms of immediate concrete effects on themselves (e.g., an action is bad if you get punished for it—Stage 1, or an action is good if you get something desirable out of it—Stage 2). As children become more cognitively mature, they come to understand that other people have interests that differ from their own, that these may also vary from person to person, and that good and bad reflect an interplay among the array of interests. At the highest level, people understand that morals are higher-order abstract principles that promote smooth functioning of the society at large and are based on reciprocal relationships marked by characteristics such as trust, loyalty, respect, or gratitude; these protect everyone, not just in the short but also in the long term. There is an understanding that morals such as, for instance, respect for life and human welfare transcend particular cultures, societies and eras. Although Kohlberg's stages may no longer be regarded as a literal and exact description of the course of moral development, they offer substantial insights into the course of moral growth and how to foster it (see below).

How Can Moral Creativity Be Fostered?

This section focuses on the contribution of education to the growth of moral creativity. The traditional approach involved teachers explicitly advocating virtues such as honesty, kindness, patience, or strength, for instance through direct communication of their belief in such virtues, by personal example, and by giving students opportunities of practising these virtues and rewarding such expression. This process was frequently supported by separate classes on moral and ethical behavior, such as religious instruction or civics. A common teaching method for doing this was to present a moral dilemma to students and ask them to work out an appropriate moral course of action. Class discussion would then focus on deviations from justice, fairness, or other moral principles.

The goal of the cognitive development approach to moral education, however, is to encourage individuals to develop to higher stages of moral reasoning. According to Jean Piaget, children understand events in their environment in ways dictated by their level of cognitive development. When they encounter new information that is inconsistent with their existing world view, they must adjust their current understanding of how the world operates in order to make sense of this new information (i.e., 'accommodate'), or else ignore the information or distort it so that it can be incorporated into their existing understanding of how things hang together, after all (i.e., 'assimilate'). The process of adjustment is called 'equilibration,' i.e., reaching a new and stable, expanded understanding of the nature of things by accommodating new and previously discrepant information. It is through equilibration that cognitive development occurs. At the heart of this model is the idea of confronting students with information contradicting their present level of cognitive development, in order to make it necessary for them to accommodate and thus reach a higher level.

In order to achieve this, writers such as Piaget argue that educators should provide students with opportunities to discover morals themselves, rather than simply indoctrinating them with norms. Kohlberg argued that moral education also requires more than individual reflection, and should include students functioning within a community. This could be done by emphasizing cooperative decision-making and problem solving, in order to make it possible for them to work out for themselves ethics based on fairness, consideration for others, altruism, loyalty, and the like. The 'infusion' approach emphasizes that, rather than simply being an add-on, education offering such experiences should permeate the entire school experience. It is not a competitor with or an ancillary to the acquisition of academic knowledge and skills, but supports this process: responsibility, respect for others, self-control and diligence foster academic learning. The point is to convey to young people an image of the kind of people the particular culture admires and wants them to emulate. Teachers should speak openly of 'good' and 'bad' and of 'right' and 'wrong.' Words such as 'responsibility,' 'honesty,' 'consideration,' and 'perseverance' should be used in discussing actions and behaviors.

Infusion with moral and ethical issues seems most obviously possible in language arts, social studies, history, and similar areas, but it is also possible in science, sport, technology education, and similar areas of curriculum, where honesty, consideration for others, fairness, ethically-acceptable behavior, and similar values can be discussed. Infusion also involves out-of-class activities, even behavior in the schoolyard, the toilets, the locker room or the lunchroom. Infusion involves the development of a positive moral climate in an entire school. A related approach is service learning, in which children are given classroom chores such as passing out library books or straightening the desks and chairs, at the simplest level, tutoring or mentoring younger children later, and, eventually, performing service activities such as carrying out an internship in a seniors' residence or a day-care center.

Robert Sternberg argued that wise thinking can be developed, and outlined activities students should engage in: These include reading classic works of literature and philosophy (i.e., engaging with 'the hard-won insights of the past,' as Kevin Hilton put it), and participating in class discussions, projects, and essays that encourage discussion of the lessons to be learned from these works and how these lessons can be applied to everyday life. Sternberg also recommended particular emphasis on the development of dialogical and dialectical thinking. Dialogical thinking involves understanding significant problems from multiple points of view and

understanding how others can see things differently. Dialectical thinking involves understanding that ideas pass from the past to the present and from the present to the future. Students need not only to acquire factual knowledge, but also to develop their own values through reflecting upon such knowledge. Instruction should place greater emphasis on critical, creative, and practical thinking that benefits not only the individual doing the thinking but others as well. Students would be encouraged to think about how almost everything they study might be used for better or worse purposes, and to realize that the ends to which knowledge is put do matter. Sternberg and colleagues have constructed a program for teaching American History based on these principles.

Concluding Remarks

Despite the commonly voiced view that creativity is beyond questions of virtue and wickedness, to paraphrase Sternberg, the ends to which creativity is put *do* matter. We need concepts that make it possible to distinguish between the creativity of people who bring great benefits to humankind in both artistic/aesthetic domains (fine art, literature, music, and the like), as well as in technology, business, science, public administration, and similar areas, and the creativity of those whose creativity harms other people. Moral precepts provide guidelines on how to do this. Although morals are, in theory, arbitrary, at their core is a set of values that are shared by a wide variety of cultures over a long period of time. The heart of these is the idea of fostering the well-being of others. Thus, the application of creativity to serve narrow interests at the expense of the wider community is immoral, whereas applying it to enhance the common good is moral.

Morals are acquired, and can be taught. However, rather than being imposed by exhortation or diktat they should be worked out by each individual, and should be based on shared experiences, both of what past generations worked out and recorded in, for instance, great works, as well as on direct interactions with contemporaries, especially in activities that involve contributing to the common good. In this way, people acquire wisdom, and wisdom makes it possible for them to apply creativity in ways that balance private and common interests, and is thus moral. The purpose of placing emphasis on moral issues in creativity is not the self-righteous imposition of a rigid set of pre-specified values on the generation of effective novelty, but encouraging those who generate or use such novelty to examine their own efforts from the moral point of view.

Introduction

What factors push people to engage in creative activity? Is it caused by ambition and the need to show off or rather driven by the pleasure given by the activity itself? Are people able to behave more creatively when creating alone, or rather when surrounded by important others? Do their beliefs and values regarding creativity determine their interest and effort and, if yes, when and how? Does there come a time when a person's creative purpose and pursuits are foundational to a person's identity, driving their choice to be creative?

One view is that creativity is polimotivational – many different complementary, contrasting, and even conflicting reasons can lead to creative thinking and action. Individuals may feel ambition to be creative or pursue a creative challenge to satisfy some external pressure and find before long that they have lost—or never had—any intrinsic drive, joy, or identity with the creative activity at hand. To be clear, some factors are definitely more prominent than others when it comes to creative activity and outcomes. For instance, children and youth are highly motivated to be creative through play when conditions allow for self-directed, intrinsic curiosity to take root. Adults can be intrinsically motivated by play as well; however, especially in the professional realm, adults can be motivated toward creative achievement by more external factors, such as rewards, praise, or competition. For instance, the phenomenon of televised talent competition shows, such as *America Got's Talent*, *The X Factor*, or *Dancing With The Stars* stokes the creative fire of thousands of amateur performing artists and entertainers through a mix of contrasting intrinsic and external drivers, such as passion and competition. Understanding what motivates people to be creative is complex and requires taking multiple perspectives to understand clearly.

Classical theorizing on motivation in creativity has taken an individualized perspective, mainly positioning the motivation to be creative as the internal workings of the individual. That approach has neglected the role of the sociocultural context in shaping and sustaining the motives and beliefs of the individual engaging in the creative process (Glăveanu, 2011). In response, the field of creativity research has developed multifaceted models to understand the role of a variety of motivational factors in creative development and production. Integrated models include both ability (e.g., dispositions, knowledge, and skills), motivation (e.g., goals, experiential drive, identity, and persistence), and context (e.g., social and cultural factors). Integrated models link the environmental conditions with the person-level creative resources to understand individual differences in creative development and performance (Amabile, 1983). However, past integration of motivational theory has focused on mechanisms within the individual and largely ignored the sociocultural setting in which creative thinking and behaviors occur. This entry explores creativity research, looking for connections between motivational mechanisms and creative outcomes. Creativity research that integrates the sociocognitive perspective is presented and new potential directions in creativity research to bridge sociocultural theories of identity, motivation, and behavior noted. Those models provide new opportunities for research on the affective and motivational dimensions of creative thinking, behaviors, attitudes, and development across the lifespan.

Motivational Mechanisms and Creativity

In creative thinking and behaviors, researchers pursued a number of links between motivational mechanisms and creative development and achievement. Intrinsic interest—motivation to do something for its own sake—was studied for decades demonstrating consistent support for creative behaviors. Extrinsic motives and rewards can also enhance creative performance, depending on the context and type of reward; in some settings, however, they also may be a deterrent (Eisenberger and Aselage, 2008). An individual's self-efficacy, defined as “perceived confidence to creatively perform a given task, in a specific context, at a particular level”

and self-concept delineated as “holistic cognitive and affective judgments of creative ability in and across particular domains” (Karwowski et al., 2019, p. 399), in part, shape an individual’s affect toward a creative task. Those creative self-beliefs suggest that creative behavior can be considered as agentic action (Karwowski and Beghetto, 2018). The study of creative mindsets investigates “beliefs about the nature of creativity itself” (Karwowski et al., 2019, p. 399) integrates implicit theory research about malleability of intelligence and demonstrates a unique role in shaping motives for creative behavior and responsiveness to messaging and modeling in the environment.

In the sociocultural setting of a classroom, other forces are at play in supporting creative development, including the fundamental needs for sense of autonomy, belonging/relatedness, and competency (Anderson et al., 2019). Affective theory from neuroscience (Anderson, 2018) and psychology suggest that mood and embodied emotional states that also shape motives are at play in creative generation. Creative thinking and behavior face pressures to conform to the expectations and norms of others and requires the willingness to take risks in thinking and acting in unconventional ways. Motivational theories grounded in the sociocultural context suggest that individual motives and resulting behaviors and efforts depend largely on the dynamic construction of their identity in each context, especially in relation to a sense of belonging.

Logically, the role that creative thinking and behaviors play in an African-American students’ identity may be very different in an academic school setting with predominantly white peers, white teachers, and white, dominant-culture content than in the community-based dance classes she attends outside of school with an African American instructor and peers. Some scholars argue that social identity and shared appreciation for certain kinds of creative thinking and behavior plays a large role in motivating individuals to approach creative challenges.

Integrating Motivation Theories

Pioneering motivational theories as well as more extraordinary approaches provide different explanations for why people create. For instance, the idea that some people possess a stronger need for achievement than others could certainly explain differences in creative accomplishments. Some have found the allure of romance and sex to boost the creative output of individuals, partially as a result of enhanced affective mood and arousal, suggesting a link between sexual selection and creative production (Griskevicius et al., 2006). Clearly, a range of motivational models build from the premise that an individual’s motives and affect shape their creative process within the sociocultural context in which they think, make, act, and develop. Both the context and the person-level resources brought to that setting play a role in the individual’s pursuit of creative thinking and action in an integrated and, often, reciprocal process. Theories in motivation help to clarify how contextual conditions and the resources of the individual interact to form the motive for creative thinking and behaviors. For instance, identity-based motivation would suggest that when contextual cues activate a creative identity in an individual, they are more likely to behave and think creatively; moreover, they would be more likely to recognize challenges met along the way as normal and signifying importance (Oyserman et al., 2017). Social identity (Haslam et al., 2013) and participatory approaches to creativity urge scholars to look beyond the individual-level mechanisms that shape motivation to be creative; however, previous work in motivation theory at the individual level does provide important insights to shape future directions in research on motivation and creativity.

Self-Determination Theory and Fundamental Needs

Importantly, across age groups, extensive research indicates that intrinsic interest and enjoyment in the challenge of the work is a critical force for continued engagement and risk-taking in creative endeavors (Hennessey and Amabile, 2010). Conversely, extrinsic rewards and incentives may not consistently lead to higher creative output in the educational context (Hennessey, 2015). Yet, some research suggests that, when rewards are relevant to the task or salient to the individual, higher creative performance can result in both educational and professional settings (Eisenberger and Aselage, 2008). Generally, though, extensive research through a self-determination framework indicates that extrinsic rewards of all types—engagement-contingent, completion-contingent, and performance-contingent—undermine intrinsic interest and performance in a variety of creativity-related behaviors across age groups (Deci et al., 1999).

In contrast, positive feedback related to intrinsic interest and free-choice will likely support creative behavior. Across five different cultural contexts, intrinsic motivational factors supported creative performance, whereas, extrinsic reward was less consistently supportive for younger students (Hennessey, 2015). Some individual characteristics also influence the role of extrinsic motivation, including cultural background, gender, and personality, among others. Environmental conditions, instructional choices, types of extrinsic rewards and feedback, as well as individual characteristics shape accessibility, challenge level, and skill attainment within a creative endeavor. Those dimensions are key ingredients to generating *flow* experiences of enjoyment and immersion for the individual, which have been connected to the creative process across domains (Csikszentmihalyi, 1997).

Goal Orientation and Creative Pursuits

An individual’s goal orientation in a creatively demanding task can depend on many factors, such as external reward or social pressure, and that orientation to *mastery* versus *performance* and *approach* versus *avoidance* can dictate how a person feels and produces. A drive toward positive outcomes through a *proactive approach* orientation can promote creativity, support the individual to view

creative challenges as opportunities for self-fulfillment, and help the individual cope with setbacks and persist with resilience. For instance, research with a sample of Taiwanese junior high school students revealed links between mastery goal structure of a classroom and divergent idea production. Mastery goal structures may shape students' intrinsic and self-regulated autonomous motivations in mathematics learning further supporting greater fluency in divergent thinking (Peng et al., 2013).

Social Cognitive Theory and Human Agency in Creativity

Though creative acts take place within a sociocultural context, the individual plays a role in bringing that creative act to life. In this way, creativity can be seen as a choice with common properties to human agency—intentionality, forethought, self-reactiveness, and self-reflectiveness (Bandura, 2006). One primary facet of human agency is the prospective self-efficacy beliefs in one's ability to be successful. For instance, if one doesn't feel confident to improvise missing ingredients in a recipe, the choice to take a creative risk in the kitchen is unlikely, and the possibility for an unexpected innovation will remain closed.

New research has begun to underscore the importance of creative self-efficacy and other creative self-beliefs in shaping creative action. For instance, the link between creative potential and creative activity and achievement was explained, in part, by the level of the individual's self-efficacy (Karwowski and Beghetto, 2018). Logically, the role of creative self-beliefs links to other motivational systems, such as intrinsic interest and the personal value of being creative. For example, the creative self-beliefs of secondary school students in the United Kingdom predicted intrinsic and extrinsic motivation and literacy achievement at similar levels (Putwain et al., 2012).

In addition to self-efficacy, an individual's locus of control and valuing of the task are other aspects of the SCT model of human agency, each with rich theoretical and empirical work and clear implications for creativity. For instance, from a SCT perspective, the social and contextual modes of agency require greater attention in creativity research, especially in the educational context. Personal valuing of creative attitudes, such as risk-taking, and creative thinking and behaviors links to expectancy-value theory, which has been largely ignored in creativity research. However, the costs and risks of being creative are often real and such cost-benefit analysis exists whether or not it occurs consciously. From an expectancy-value perspective (Wigfield, 1994), creative thinking, attitudes, behavior, and accomplishments will have four different components of subjective value: (a) the attainment value as the importance of doing well in the creative endeavor; (b) intrinsic value in the form of pleasure and fulfillment in the activity (similar to SDT framework); (c) utility value or usefulness in the current and future plans and goals of an individual; and (d) cost value, which refers to what an individual needs to give up in their choices for creative thinking and engagement. Though underutilized in research on motivation and creativity, this level of specificity to operationalize value in creative agentic action may be helpful for future research from a sociocognitive perspective.

New Directions for Motivation and Creativity

Though identity and creativity have been studied through a variety of frameworks, there has not been an emphasis on the connection of identity, context, and motivation in creative pursuits. Identity-based motivation theory provides an opportunity to theorize in this interconnected approach. Identity-based motivation bridges multiple motivational models within a situated and sociocultural perspective conceptualizing the self as a moment-to-moment dynamic construction of identity based on the individual's experience within a specific environment. From that perspective, the self is comprised of content (e.g., how creative one might think they are and how likely they are to be creative in a certain task or context) and metacognitive process (e.g., how one feels in creative thinking and action). As such, identity-based motivation provides a "social-psychological theory of human motivation and goal pursuit. It explains when and in which situations people's identities and self-concepts motivate them to take action toward their goals" (Oyserman et al., 2017, p. 140). In this way, identity-based motivation may provide creativity research a lens to learn more about the connection between identity, motives, context, action, and performance.

Three main features of identity-based motivation are important to consider in relation to the study of motivation and creativity in context. First, identity-based motivation assumes that the immediate context is capable of shaping an individual's identity in a process of dynamic construction that shapes action and thought—meaning *identities have value*. Second, individuals are likely to act in ways that are congruent with the constructed, and currently active, identity, preparing them for action—meaning *identities are for action*. Third, if goal pursuits and actions align with that identity, then the experience of difficulty faced in that activity will mean that challenges are normal and expected. When there is incongruence between identity, goals, and the activity, difficulty will be interpreted as diagnostic of the individual—meaning the activity is *not for people like me* (Oyserman et al., 2017).

In creative thinking, attitudes, and behavior, the premise of identity-based motivation aligns to the sociocognitive model of creative behavior as agentic action and extends that model to consider how the dynamic construction of a creative identity will be determined, in part, by the nature of the context. According to an identity-based motivation perspective, how an individual approaches an opportunity or challenge for creative thinking, attitude, and action depends on the congruence between their active identity and the context and activity—*do they know themselves to be creative in that context*. When they meet an obstacle in that creative endeavor, that congruence or incongruence will determine how they interpret success and failure. The identity construction process and resulting congruence will be determined by subtle cues in the environment that may define who is considered creative and what kinds of creative thinking and behaviors are valued or not. Identity-based motivation can respond to recent calls in the educational psychology and creativity fields to integrate the complexity of race, culture, gender, and other dimensions of identity and social

behavior into theory, practice, and research (Glaveanu et al., 2019). Additionally, recent framing of links between identity development and creativity in adolescence provide three pathways to consider—identity exploration as a parallel to divergent thinking; creative self-expression as a process of identity discovery; and creative commitments as a buttress to healthy identity commitments (Barbot and Heuser, 2017). Identity-based motivation may provide an exemplar model to integrate into future research on creativity and motivation.

Fortunately, a growing body of research has demonstrated the effects of identity-based motivation on important motivational and academic outcomes (see Oyserman et al., 2017, for a review) and provides model intervention strategies to test the theory in practice. Results to date suggest that the theory plays out in the reality of young people in an educational context. These studies randomly assigned students to a condition or set of conditions that reflected one or more aspects of identity-based motivation, such as amplifying a contextual cue to activate the construction of a particular identity (Elmore and Oyserman, 2012). Another study manipulated the fit between identity and context (Oyserman et al., 2015) and another altered a contextual cue to be more immediate and relevant in the student's future self (e.g., Nurra and Oyserman, 2018). Advances in identity-based motivation theory provide important pathways for creativity scholars to pursue, regarding the role of identity, context, interpretation of difficulty, and action readiness across different developmental stages and in different contexts. Naturally, this approach to studying motives for creative thinking and action is situated in the sociocultural context from which creativity will arise and be recognized.

Conclusion

Contemporary theorizing in motivation and creativity has shifted a focus toward the interaction of the individual and the context providing new ways to conceptualize why people think, act, and develop creatively at different stages of life. Though more classical motivation theories, such as need for achievement, self-determination theory, and social-cognitive theory, shed light on the issue of why people create, those theories generally focus on the individual, ignoring much of the context surrounding the individual. When the sociocultural context is ignored, what may look like a lack of motivation to create could actually be a protective factor in response to heightened risk or pressure to conform to dominant cultural norms. In this way, research may begin to shift the question from *why do we create* to *when and where do we create and why?*

Introduction

If we select a sample of undergraduate students and ask them the following questions: Who invented the telephone? Who invented calculus? Who created the periodic table? and Who invented the telescope? Most of them will be able to answer Alexander Graham Bell, Isaac Newton, Dmitri Mendeleev, and Galileo Galilei respectively. Perhaps this reflects an educational system that prefers one correct answer for one question. However, the broader truth to the questions mentioned above is that all these discoveries (and others) were invented, created, or designed by more than one person. This is a phenomenon known in the scientific discovery literature as *multiple discovery* (Merton, 1961). Although this phenomenon and the controversy surrounding it started in the 17th century, the debate reached a peak in the 20th century among four groups of scientists: historians, sociologists, psychologists, and philosophers. These four groups of scientists offered somewhat different explanations for the multiple discovery phenomenon. While philosophers supported the logic theory, historians and sociologists supported the zeitgeist theory. The psychologists were divided into two groups: one claiming that multiple discovery could be explained by following logic (Simon and Newell, 1971) and the other group claiming that multiple discovery could be explained by the genius theory. Yet, among psychologists a third interpretation emerged when Dean Keith Simonton discussed the role of chance in scientific discovery (Simonton, 1979). Thus, there are at least four competing theories for multiple discovery. In this article the term *multiples* will be used in place of multiple discovery. First, it is necessary to discuss the phenomenon of *multiples* as it resides within the context of creativity, which hopefully will clarify some subsequent issues related to *multiples*. The third section in this article offers examples of *multiples* that originated within three different domains: (a) agriculture, (b) psychology, and (c) chemistry. The fourth section of this article discusses the four competing theories of *multiples* in detail. The fifth section discusses the possibility that all these theories of *multiples* can be valid to some extent. A brief discussion on the future of *multiples* is offered.

Multiples Within the Systems Model of Creativity

One of the major theories in creativity research is the systems theory (Csikszentmihalyi, 1990), which consists of three interactive components: the person, the field, and the domain. The broadest component, the domain, represents the body of knowledge within each discipline such as arts, mathematics, science, and social studies. This body of knowledge includes theories, methods of studying different phenomena, assessments, facts, and indeed problems that need to be tackled by those working within the domain. The fundamental component, the person, represents individuals studying in each domain. After acquiring a high level of expertise within the domain through studying, attending conferences, mentoring, and other means of acquiring knowledge, only a proportion of those individuals will come up with new and useful ideas that might advance the domain. Yet, ideas generated by the person are subjected to scrutiny by the third component of Csikszentmihalyi systems' model, the field. The field refers to the experts or gatekeepers who decide whether an idea, proposition, or product generated by an individual is creative or not. If the field accepts the new idea, then it becomes a part of the domain. Of course, not all individuals working in the domain have the ability to produce original and useful ideas that can take the domain a step further or revolutionize the domain. Beside expertise, the ability to find novel problems characterizes those individuals who raise new questions rather than solving well-defined problems. Indeed, there is a big difference between problem finders and problem solvers.

The systems' model can explain *multiples* in at least two ways. First, as indicated above, each domain consists of pool of ideas or problems in which more than one scientist (person) is trying to solve; hence, it is possible that within any domain, two or more scientists will be working on the *same* problem. Second, domains differ in the number of researchers, or what can be called the domain population. It is, therefore, expected that the larger the domain, the more the possibility that two or more scientists will be working on the same problem compared with other domains consisting of small number of researchers. The link between the systems' model and *multiples* will be discussed with more details in the chance theory of multiples below. After understanding the concept of creativity within the systems' model, it is now appropriate to give some examples of *multiples*.

Examples of Multiples

The objective of this section is to offer some examples of *multiples*. Among famous *multiples* are the steam boat, the theory of natural selection, the invention of electric motors, the telegraph, the law of conservation of energy, the invention of photography, the microscope, the telescope, the discovery of oxygen, and the invention of calculus. In fact, the number of *multiples* cases are abundant. Thus, the plan is to give three examples from three different domains.

The first example is the discovery of the first hormone herbicides. A herbicide is a chemical used to kill unwanted plants. For instance, killing weeds but leaving the corn or soybean crop unharmed. This is an interesting example of *multiples* because four groups of agriculture scientists did discover it and it revolutionized modern agriculture. Interestingly, two groups in the United Kingdom (William Templeman and Philip Nutman) and two groups in the United States (Franklin Jones, and Ezra Kraus & John Mitchell) made this discovery simultaneously. Their research was conducted during the World War II, with all four groups of discoverers unaware of other's works (Troyer, 2001). Due to the difficulty of publishing articles during wartime, none of the four groups of scientists had published their discovery. The discovery of first hormone herbicides was first published by not original discoverers, but by others who came later (Troyer, 2001). What is significant about this discovery is that hormone-like herbicides such as 2, 4-D, 2, 4, and 5-T can selectively kill many weeds at a low cost. In this example, the lack of communication between the four groups of scientists should be noted, because it explains this instance of *multiples*. Consequently, we can expect that the frequency of *multiples* would decrease with the growth of communication. In the 21st Century, the communication among researchers has increase exponentially.

Although the search for *multiples* has been in fields such as Chemistry, Physics, and Biology, this phenomenon is not limited to the hard sciences. The second example concerns a discovery in psychology. The rare, yet interesting case of Accidental Proneness Theory. Two psychologists who were not aware of each other's work proposed this symptom: Karl Marbe from Germany and Eric Farmer from Britain. In 1925, during the World War I, both happen to publish their theory in a local publication. By 1926, Marbe and Farmer published a comprehensive version of their theory of accidental proneness. Accidental proneness proposes that some people are more inclined to be injured than others. Both Marbe and Farmer used statistical probability to prove this phenomenon. Marbe and Farmer found that the probability of having a future accident was greater for those who had had an accident in the past (Burnham, 2008). According to accidental proneness theory, accidental injury and accidental illness are not normally distributed. Regardless whether we agree or disagree with this theory, this case study is an example of a *multiples* in an area other than the hard science. However, Simonton suggests that the occurrences of *multiples* in psychology are rare events compared to large-scale fields such as medicine and psychics (Simonton, 2004).

One of the most famous examples of *multiples* in chemistry is the creation of the periodic table by at least six independent scientists: Stanislao Cannizzaro, John Newlands, William Odling, Gustavus Hinrichs, Julius Meyer, and Dimitri Mendeleev. This case represents multiple discovery rather than simulations discovery, since different scientist discovered it over a period of seven years. Cannizzaro, an Italian chemist, published a three-dimensional periodic system, but his contribution was unknown partly because the publisher of his work did not publish Cannizzaro's full work. What was unpublished was the most critical element of the paper, the diagrams. The second discoverer, Newlands, a British chemist submitted for publication an article presenting a periodic table with 24 elements. However, his contribution was criticized by gatekeepers and thus rejected for publication. In light of systems theory of creativity, this discovery was rejected by the experts and thus failed to enter the domain. The third discoverer, Odling published a more comprehensive table compared with Cannizzaro and Newlands' tables, which consisted of 57 elements. Nonetheless, his contribution was unknown because he was more interested in fundamental science rather than classifying chemical elements. He stopped developing his original work. Hinrichs, another discoverer who was born in Germany made a significant contribution by realizing the periodic law, which paved the way for the periodic table. In fact, Hinrichs grouped the copper, silver and gold elements that were ignored in Mendeleev's earliest periodic table. Hinrichs final version of periodic table included 50 elements, but unfortunately his contribution was unrecognized because his work went unpublished for 25 years. Finally, Mendeleev, who got the lion's share of credit among those six discoverers, developed a more exhaustive periodic table consisting of 63 elements (Scerri, 2015). These three instances of *multiples* in different domains provides a backdrop to the theories of *multiples*.

Theories of Multiples

The Zeitgeist Theory

The concept of zeitgeist captures the notion that ideas come to fruition because they are nurtured by a particular period in history. Ogburn and Thomas (1922) who listed 148 significant cases that were made by two or more discoverers conducted the first empirical investigation supporting this notion. According to this point of view, it is the 'times' or zeitgeist that allowed Galileo, Fabricius,

Scheiner, and Harriott to discover sunspots in 1611; Stokes and Seidel to invent the principle of uniform convergence in 1847; and Darwin and Wallace to posit the theory of natural selection in 1858 (Ogburn and Thomas, 1922). These individuals made these discoveries simultaneously and from different locations. They were not aware of each other's work. For example, the discovery of sunspots was made in four different countries (that is, Italy, Germany, Holland, and England) in the same year. It seems that sunspots and other discoveries were made because the technical and cultural times were ripe for them (Merton, 1961).

The zeitgeist interpretation of *multiples* was based on five assumptions: (a) the incremental accumulation of knowledge, (b) the social interaction between scientists, (c) the systematic procedures of inquiry, (d) the idea that inventions are birth of time, and (e) that all scientific discoveries are in principle *multiples*. Collaborative discovery is the norm, and individual insight is the exception. It is singletons that need to be explained (Merton, 1961). However, other groups of scientists criticized sociologists over their interpretation of *multiples*. Is the claim that scientific discoveries are in principle multiples a valid claim? As mentioned earlier, the most comprehensive list of *multiples* was generated by Simonton (1979) with 579 cases. How about the thousands of discoveries that were made by a lone originator? One data source to consider is the US Patent and Trademark Office (USPTO). According to one report published by the USPTO, in the period 1975–2015 the lowest number of inventions occurred in 1983 when 10,548 inventions were filed for patents. These numbers show that the sociologists' claim that multiple scientific authors are the norm is not a valid one. Sociologists of science seem to underestimate the role of individual differences in scientific discoveries.

Many of the intellectuals who were involved in *multiples* demonstrated exceptional abilities. When Isaac Newton was 18 he entered one of the most prestigious schools in Europe, Cambridge University. In his 20s he delineated the foundations for theories of math and physics that eventually revolutionized the world (Hart, 1992). Newton's exceptionality was witnessed by his antagonist, Leibniz, who wrote 'Taking mathematics from the beginning of the world to the time when Newton lived, what he has done is much the better part' (as cited in Hart, 1992, p. 14). Newton and many other scientists were involved in more than one multiple discovery. This might be considered evidence that an individual has to be exceptional to originate a new discovery, multiple or lone.

However, some argued that the lone inventor is a myth, this might not be the case. Francis Bacon and Alan Turing are two examples that fit the profile of 'lone wolf.' Robert Merton (1961) devoted a great deal of his 1961 article talking about Bacon's genius and exceptionality:

No economist, Bacon could in 1615 originate the concept of balance of trade. No great admirer of mathematics but cognizant of the value of quantification, he could write as he did generations before the extraordinary London haberdasher John Graunt, Sir William Petty, and Gregory King could among them fashion the new political arithmetic and so initiate the serious study of demography, urban sociology, and epidemiology. (p. 470)

Furthermore, Merton argued that Bacon legitimized the social sciences at least one and a half century before Auguste Comte, the father of sociology. Similar in achievement, Alan Turing 'sketched the essentials of digital computers about 10 years before these were actually in existence' (Mackworth, 1965, p. 52). Thus, it seems that the zeitgeist's interpretation of *multiples* is incomplete, because Bacon and Turing seem to tower above their 'time.'

The Genius Theory

Genius is somehow a difficult term to define and has often been used in a misleading manner (Simonton, 2004). One of the difficulties stems from the stereotype that links genius with madness, or from perceiving genius as source of inspiration from gods. Although the link between genius and some kinds of mental illnesses is still controversial, the latter perception of genius has been rejected with the establishment of scientific methods in the 19th and 20th centuries (e.g., Galton, Freud, and Terman). It is important to define the construct genius before discussing the genius theory of *multiples*. Genius is not a dichotomous concept in which people are classified into two categories, those who are genius and others who are not. Rather, genius can be put on a scale, or as Simonton (2004) asserted: 'Variation is a matter of degree rather than kind' (p. 18). Therefore, it is not acceptable to say that Newton was a genius where Leibniz was not.

The genius theory, unlike the zeitgeist, accounts for individual differences between scientists. According to this point of view: not everyone can significantly contribute to the advancement of science, and *multiples* are neither the result of accumulated knowledge nor the result of using logic to a high degree. Indeed, logic is important in any creative problem-solving effort; however, logic is insufficient to generate new and unusual ideas. This led some proponents of the genius theory to claim that great scientists have the capability to dispense with logic (Simonton, 2004). But how can genius can be operationally defined? According to Albert (1975) a genius is 'anyone who, regardless of other characteristics he may possess or have attributed to him, produces, over a long period of time, a large body of work that has a significant influence on many persons for many years' (p. 144). A key point in Albert's definition is that a person of genius has the ability to be productive and influential over a long period. Thus, one way to assess genius is to examine productivity in terms of publications. Two important issues related to publication provide a way to assess individual differences among scientist. First is the number of publications scientists produce in their careers. If the all publications are considered equal, the number of publications provide a way to assess scientific achievement. However, it is the quality of research that makes a difference. For instance, Einstein published more than 300 papers through his career, yet only five of his top publications are responsible for 35.5% of citations he received. This is a pattern that Simonton (2004) called the equal-odds rule. The equal-odds rule asserts 'scientists who publish the most highly cited works also publish the most poorly cited works'

(p. 22). Overall, according to the genius perspective some scientists are prolific, consequently, they should be involved in more *multiples*. The genius theory supports the proposition that it is individual differences rather than the spirit of time that accounts for unique discoveries. Yet, how do great scientists come up with original ideas and products? In other words, what distinguishes a man of genius from others? Perhaps the chance theory can help answer this question.

The Chance Theory

The term chance has different meanings. On one hand, chance is defined as ‘the occurrence of events in the absence of any obvious intention or cause’ (Oxford Dictionary of English, 2010). Related to *multiples* are accidental discoveries, that is, when someone was looking for something and then found something else. For example, Roberts (1989) listed 36 accidental discoveries such as the DNA, Penicillin, X-rays, and Columbus’ discovery of the ‘new world.’ On the other hand, chance is defined in terms of probability, finding a new idea through a combinatorial process. A combinatorial process, as it relates to discoveries, can be defined as any mechanism or procedure by which two or more concepts are put together to form a novel combination. Typically, this process entails a search through a range of combinatorial possibilities. Examples of combinatorial models in creativity include Mednick’s associative theory and Campbell’s blind variation and selective retention theory (Runco, 2014). Simonton (2009) discussed in detail how *multiples* could be a result of a combinatorial process through six assumptions.

First, individuals build their knowledge of a particular subject from different sources such as formal education, books, conferences, media, and other sources of knowledge. The subject knowledge that an individual acquires represents a sample of ideas from the larger subject domain (that is, mathematics, physics, psychology, etc.). For individuals working within the same domain, some of the information, facts, and theories will be recognizable and shared. However, not all individuals within a subject domain will share the same level of knowledge. It is expected that there will be differences due to different texts, different instructors, different kinds of training, and so forth.

Second, it is supposed that intellectual and dispositional traits will be randomly distributed regardless whether the size of the domain is large such as mathematics or small such as special education. The third assumption asserts that domains vary in their size. While large fields have many researchers who are actively engaged in solving problems or identifying research questions, other fields may have fewer researchers. Fourth, those active members within each field are subject to quasi-random combinatorial process, that is, they engage in various type of interactions that provide additional knowledge acquisition. Fifth, ideas generated through combinatorial process vary in terms of quality with high quality ideas being rare compared with ordinary ideas. Finally, these ideas generated through combinatorial process are translated into a product via publications, which must be communicated to the field (i.e., expert scientists). As indicated earlier in the systems model of creativity, once new ideas are accepted by the field, they become a part of the domain. The influence a particular academic idea has depends on many factors such as publication type (e.g., books, peer-review articles, magazines, theses, or dissertations) or journal status (major or minor). To summarize, according to the chance interpretation of *multiples*, the occurrence of simulations discoveries can be attributed to quasi-random combinatory processes. This perspective is far from the logic theory of scientific discoveries to which I will now turn.

The Logic Theory

Contrary to the genius perspective, the logic theory of *multiples* asserts that a scientific discovery can be conceived as a logical step-by-step process. In fact, Herbert Simon through his experiments with computer programs provided evidence that discoveries can be predicted by using logic. Among the different programs he and his colleagues developed, BACON seems to be the most famous one. Successfully, BACON rediscovered a number of discoveries such as Snell’s law of refraction, Black’s specific heat law, and Kepler’s law of planetary motion (Bradshaw and Simon, 1981).

Moreover, the logic theory treats *multiples* as kind of problem solving. Like zeitgeist theory, the logic perspective does not account for individual differences in scientific discoveries. According to the logic interpretation of *multiples*, anyone can make discoveries, if he or she employs a step-by-step method that is based on logic. This view of scientific discoveries received criticism. First, the logic interpretation of scientific discovery ignores the role insight plays in scientific discoveries. There is evidence in the creativity literature showing that insight or the aha moment, or illumination as Graham Wallace named it, is part of creative problem solving. Second and more importantly, computer problem solving deals only with well-defined problems. Real life problems are not always well defined. In other words, computer programs can solve problems, but they cannot find problems. Indeed, logic and reasoning are important elements of any creative problem-solving effort. Most models of the creative process include elements related to logic and convergent thinking; however, logic is not sufficient for creative behavior. Therefore, most scholars in creativity field reject the idea that creativity is nothing but problem solving.

Among the Four Interpretations Who Is Right? and Who Is Not?

The past century witnessed a heated debate between four groups of researchers, each trying to demonstrate that their interpretation of *multiples* is more accurate and valid than the other. In fact, none of these four interpretations can fully explain the occurrence of *multiples*, although the chance theory seems to be more precise and coherent compared to the three other perspectives - zeitgeist, logic, or genius. Therefore, instead of adopting one interpretation and thus, asserting that other explanations of *multiples* are invalid,

this article concurs that all four perspectives can be integrated (Simonton, 2004). By using the concept of creativity that embodies the times, individual inspiration, logic, and chance. For most definitions of creativity, the idea or a product must meet two simple criteria, originality and appropriateness. This can be applied to scientific discoveries. First, no one can ignore the role of logic in scientific discoveries. Both divergent and convergent thinking are important for creativity and creative thinking. Yet, logic is important but insufficient to explain or to predict scientific discoveries. Furthermore, creativity is not synonymous with problem solving, especially the kind of problem-solving Simon implies that only requires using logic. Second, it is inappropriate to deny the intellectual and dispositional abilities of discoverers who were involved in *multiples* such as Newton, Darwin, Galileo, Mendeleev, and others. In other words, they were not ordinary individuals as their bibliographies showed.

According to Hart's ranking of the most influential persons in history, Newton rank was 2, Galileo was 12, Darwin was 16, Edison was 35, Graham Bell was 42, and Mendel was 58. Third, with very few exceptions such as Bacon and Turing, the advancement of science is predominately based on accumulated knowledge. This is consistent with one of Simonton's assumption that each individual in any domain can acquire a sample of the domain's knowledge. This sample of knowledge then helps the discoverer combine two or more ideas in order to discover something new and valuable. If we combine the lists of *multiples* generated by Ogburn and Thomas, Merton and Barber, and Simonton, the total cases of *multiples* will be 911 cases, against thousands of singleton discoveries. Thus, the claim of sociologists that singletons are an anomaly that need to be further studied is an invalid one. Finally, the chance interpretation is first among equals because it can account for the mental processes that can lead to creative discoveries and it does not deny the role of accumulated knowledge. Furthermore, the chance perspective reported four kinds of evidence, which shows that combinatorial models can explain *multiples*. First is the distribution of multiple grades. Multiple grades refer to the number of discoverers involved in any case of *multiples*. If the zeitgeist interpretation of *multiples* is valid, then one expects that more individuals will be involved in any case of *multiples*. That is, the frequency of octuplets (8) will be higher than septuplets (7), and the frequency of septuplets will be higher than sextuplets (6), and so on. However, examining the list of Ogburn and Thomas revealed that 89 of the cases were doublet, 36 were triplets, 9 were quadruplets (4), 7 were quintuplets (5), 2 were sextuplets (6), 3 were septuplets, and 2 were octuplets. In other words, the majority (60%) of these discoveries were made by two discoverers.

The same observation was made by Simonton (1979) where 449 (77.5%) out of 579 cases were doublets. Moreover, a new method for identifying *multiples* in scientific publication was proposed by Bikard (2012) who used co-citation proximity. The method is straightforward: if two or more publications were published within one year containing same ideas, this can be an evidence of *multiples* or as Bikard (2012) called it, paper twins. Paper twins were detected using an algorithm that matches papers based on their date, authors, and citation patterns. According to Bikard (2012, p.13), 'paper twins are all pairs of research articles having no author in common, written no more than one calendar year apart, being frequently cited by the same papers and being consistently cited adjacent to each other (in the same parenthesis).' Out of thousands of publications from 1970 to 2009, only 720 papers were identified as paper twins. Not surprisingly, the majority of the 720 paper twins were doublet (70.1%), which is consistent with the multiple grade distribution Simonton (2004) suggested. The second is the temporal separation of *multiples*. Inventions, according to the chance theory indicates that the frequency of *multiples* will be higher in discoveries that happen in the same year than *multiples* that takes years between the first and last discoveries.

For the purpose of this article, Ogburn and Thomas (1922) list was scrutinized for the time lag between discoveries. The method was as follows: for doublet discoveries, the time lag between the first and the last discoveries was calculated. For triplets and above, the time lag was calculated between the first and the last discovery. The result shows that 84 (56.7%) of discoveries were made within four years; a finding supporting the chance theory. Third is the degree of multiple identity. That is, to what extent are discoveries made by two or more discoverers identical.

Discoveries that are fully identical are very rare, if they exist at all. For example, although the Italian physicist Antonino Lo Surdo and the German physicist Johannes Stark simultaneously discovered the discovery of the influence of a magnetic field on spectral lines (Stark effect), those two physicists came from different contexts: classical theory and quantum theory respectively. Finally, the chance theory of *multiples* asserts that individuals involved in one discovery will be highly likely to involve in other *multiples*. Among the 148 cases of *multiples* Ogburn and Thomas (1922) listed, Galileo was involved in seven *multiples*, Newton involved in five *multiples*, Gauss involved in four *multiples*, Laplace involved in four *multiples*, Bradley, Delambre, and Darwin were all involved in two *multiples*.

The Future of Multiples

The main question to be answered here is: will the phenomenon of *multiples* continue to appear in the future? More specifically, will we witness more or less cases of *multiples* in the next 100 years? Perhaps a safe answer will be: it depends. First, if the lack of communication between scientists in the last centuries can explain a proportion of *multiples*, then we expect this phenomenon will decrease with the advancement of communication technology. Scientists from all around the globe can find out whether their ideas were discovered or filed for patent by other scientists. This can be done by searching research databases and patent offices, looking at scientists' websites, or simply by searching Google. Moreover, researchers now can communicate their projects before submitting them to peer review journals through different means such as conferences, websites, ResearchGate, and other means of communications. Second, if the logic interpretation of *multiples* is correct, then the phenomenon of *multiples* will disappear with the unprecedented advancement in the artificial intelligence technologies. That is, computers will discover and solve problems humans will take on a servicer role. Adopting the sociologists of science interpretation of *multiples*, *multiples* will continue to appear since each

discovery depends on the incremental accumulation of knowledge, which is ever increasing. Finally, according to the chance theory of *multiples*, the frequency of *multiple* cases will depend on a number of factors such as the size of the domain. The frequency of *multiples* will be greater in fields where there are many researchers compared to fields of study that have few researchers. It might be interesting to examine the correlation between the size of domains (i.e., individuals working in a particular domain) and the frequency of *multiples*.

To conclude, the chance theory seems to be more comprehensive and convincing than the other three interpretations of *multiples*; since it considers the role of knowledge in discoveries, the individual differences between scientists in terms of abilities and dispositions, and the mental processes required to generate new ideas that lead to creative discoveries. The systems theory, which consists of three interactive components (the person, the field, and the domain), provides an encompassing starting point for the investigation into the origins and nature of scientific discoveries.

Glossary

Consonance: When two or more musical tones sound pleasant and stable, due to simple mathematical relations among their respective pitches (as in the notes C and G).

Counterpoint: When different melodic lines in a musical composition proceed simultaneously yet are independent in rhythm and contour. Counterpoint may also refer to compositional 'rules' that guide how composers are supposed to weave together different melodic lines.

Dissonance: When two or more musical tones sound unpleasant and unstable, due to more complex mathematical relations among their respective pitches (as in the notes C and F-sharp).

Dynamics: The relative loudness versus softness of musical notes.

Form: The large-scale patterns by which musical compositions are organized. For instance, symphonies involve much more complex and varied forms than songs.

Harmony: The aspect of music involving combinations of notes, usually into chords (like a major chord consisting of the notes, C, E, and G, or a minor chord consisting of the notes C, E-flat, and G). Harmony may refer to listeners' perception of chords in a piece of music, or to compositional 'rules' for combining notes and transitioning from one chord to another.

Instrumentation: How the notes of a musical composition are allocated to different musical instruments in an ensemble.

Rhythm: The timing of successive notes in a musical composition, in terms of short versus long note (and rest) durations, as well as how those notes map onto an underlying pulse or meter for the composition.

Melody: The sequence of pitches in a piece of music, which are perceived as a unified entity.

Pitch: How high or low a particular note in a musical composition is, given by the mathematical frequency of sound waves associated with that pitch.

Tempo: How slow or fast the basic pulse or beat of a musical composition is.

Timbre: The 'tone color' of a musical sound, which is typically associated with differences in the instruments producing the sound. A clarinet and a violin may play the exact same note, but the different identifiable 'sound' of each instrument reflects its unique timbre.

Introduction

Music is a culturally ubiquitous outlet of human creative expression. Musicality has been identified as a fundamental domain of the mind (Feist, 2004) and figures prominently in debates about the evolutionary origins of modern humans (Justus and Hutsler, 2005). *Homo sapiens* has probably engaged in music for our entire existence as a species, with archaeological evidence for musical instruments dating back to at least 42,000 years ago. In contemporary society, the annual worldwide revenue of the music industry is measured in the billions of dollars, and some surveys suggest that the average person spends some 40% of their waking lives listening to music. From medical and humanistic perspectives, music's ability to entertain, inspire, and heal is well documented.

Creativity is a pervasive aspect of human musicality. Many standard concepts in the mainstream creativity literature straightforwardly apply to music. These include the so-called six P's of creativity (process, product, person, place, persuasion, and potential), theoretical accounts including developmental, cognitive, and systems views, and levels of creative achievement

(see Kozbelt et al., 2010). The latter range from so-called mini-c to Big-C creativity (Kaufman and Beghetto, 2009) and represent the difference between someone privately humming a new tune versus enduring cultural monuments like Beethoven's nine symphonies.

Musical creativity has a constellation of unique qualities that sets it apart from creativity in many other domains. Music itself is evanescent, quickly passing out of personal and cultural memory unless notated or recorded. To the extent that music is an evolutionarily rooted aspect of our human nature, it differs starkly from completely invented artificial domains like chess. Individual differences in musical talent are very prominent, yet acquiring musical expertise takes years of intensive effort (Ericsson, Krampe, and Tesch-Römer, 1993). In practice, musical creativity often departs from the stereotype of a solitary person writing a tangible, definitive work; collaborations and distributed cognition, especially involving performance, are much more common. Creativity may reveal itself in musical composition, improvisation, expressive performance, and even listening. The striking pluralism of musical practices in the contemporary world has led some to question the appropriateness of the singular term 'creativity' in music, suggesting as alternatives 'musical creativities' or 'musical invention.'

The goal of this article is to explore the creative domain of music from the perspective of contemporary creativity research. Musical creativity is first explored from domain-general and domain-specific perspectives, which inform receptive versus productive or performative aspects of musical creativity, respectively. Next follows a discussion of the creative process in music, which has been illuminated by a variety of methodologies. Last comes a discussion of socio-cultural aspects of music and the complex dynamic resulting from common regularities in musical styles and systems, versus the drive for musical innovation. Throughout, the most prototypical creative practices – composition, and to a lesser extent, improvisation – are emphasized, though many of the principles would apply to other musical activities as well.

The Domain of Music

What is the scope for discussing creativity in the domain of music? Many definitions of music have been offered. One representative entry is "the capacity to produce, perceive, and appreciate rhythmic and melodic sounds that evoke an emotional response in oneself and others" (Feist, 2004, p. 61). Most definitions emphasize the production and perception of patterns rooted in basic acoustic parameters like pitch, dynamics, tempo, timbre, rhythm, and so on. Such parameters can be organized into a nearly infinite number of ways, and musical creators' (and interpreters') fecundity in conceptualizing and elaborating musical ideas raises the issue of how best to demarcate the 'domain' of music as a circumscribed area of study.

Domain-generality Versus Domain-specificity in Musical Creativity

The dilemma of how to characterize a domain of creativity is neither new nor unique to music. Indeed, a venerable debate concerns whether creativity is better regarded as more domain-general or more domain-specific. Domain-generalists argue that creativity largely results from all-purpose cognitive mechanisms, including divergent thinking, flatter associative hierarchies, regression into primary process cognition, tolerance for ambiguity, ideational abilities, and creative potential. Evidence for domain-generality typically involves collecting psychometric or personality data and self-report inventories (Baer, 2010) and assessing their predictive validity for real-world creative achievement (Plucker, 1999). On a domain-general account, musical creativity would emerge out of the confluence of such cognitive mechanisms, channeled – for some reason – into musical activities.

In contrast, the domain-specific view argues that general psychological mechanisms are inadequate to explain creative accomplishment; instead, non-transferable knowledge and skills within some domain are required. World-class achievement in complex domains invariably demands enormous effort (Weisberg, 2006). The effects of expertise acquisition are profound. Accomplished music performers differ significantly from non-musicians in neurological, cognitive, physiological, and perceptual-motor terms (Lehmann and Gruber, 2006). Even the greatest composers are not immune, as they typically require at least a decade of intensive study before producing original masterworks (Simonton, 1991).

Additional evidence supporting domain specificity comes from special populations. These include persons with congenital amusia, who are largely unable to process musical information, despite otherwise normal mental functioning, persons with Williams syndrome, where musical abilities are enhanced despite general cognitive impairments, and cases of exceptional musical prodigies, whose talent often emerges earlier than in any other domain.

Without pretending to resolve the generality-specificity debate, a domain-specific stance may be regarded as more useful for studying *productive* and *performative* aspects of musical creativity, while a domain-general stance may be more useful for music's *receptive* aspects (Kozbelt, 2017). Given the traditionally greater emphasis on composition (and improvisation) as the clearest manifestations of musical creativity, much of the ensuing discussion will have a domain-specific orientation, since expert knowledge is essential for effective composition or improvisation. However, the interaction between creators and audiences is critical for understanding socio-cultural dimensions of musical creativity, including how musical styles change over time. These themes become increasingly prominent as ambitious creators' rampant pursuit of novelty may outstrip audiences' capacity to appreciate their productions – a theme taken up near the end of the article.

Music and the Creative Process

While productive, performative, and receptive aspects of music experience can all be considered – at least to some extent – creative, composition is probably the most prototypical focus for studying creativity in music. What are the psychological processes by which music is created or composed? The creative process has long been a staple of research, via multiple methodologies; in music, these have collectively drawn a rich picture of the composer at work. Sloboda (1985) delineated three approaches to gaining psychological insight into music composition: examining written manuscripts and sketches, first-person comments about the composing process, and observation during a session of composition. Archival studies of composers' outputs have additionally informed many issues in musical creativity. More recently, neuroscience studies have likewise illuminated the nature of musical creativity. Each is discussed below, in turn.

Sketches, First-Person Accounts, and Observational Studies of Musical Creativity

Musicologists have long examined composers' sketches and notebooks as a way of understanding their methods and goals. While useful for establishing the complexity of the creative process, understanding sketches – even at the level of deciphering individual notes – demands enormous domain-specific and contextual knowledge, and conclusions remain open to interpretation, since questions about the representativeness, completeness, and chronological sequence of the paper trail can rarely be fully resolved.

Besides sketches and scores, many composers have also left provocative descriptive accounts of their own creative processes. However interesting, such anecdotes suffer from clear methodological limitations, most notably questionable representativeness and veracity, and can be cherry-picked to support virtually any theoretical position (Kozbelt, 2007). Such limitations can sometimes be overcome, but testable hypotheses are often better served by other methods.

Along such qualitative methodological lines, some researchers have investigated the nature of composers' creative processes by more systematic interview and/or observational methods. Sometimes this approach is supplemented with concurrent verbal reporting of their creative process, or analyses of sketches and works-in-progress (McAdams, 2004), to better understand the music composition process.

The fruits of such research have been some sophisticated theories about the psychological mechanisms facilitating musical creativity. Such studies have introduced a host of useful concepts in understanding the creative process in music. A menu of such concepts would include things like the interplay between divergent and convergent thinking, concurrent streams of thought, spreading activation and dissociation, chunking of processes and strategies at both micro and macro levels, a generative process of problem proliferation and successive solution implementation, synoptic planning versus heuristic ideation, generating rules in the course of music writing, cycle development and concern of coherence, and creative borrowing. Basic mechanisms and processes like these play out in several regimes of creative thought. For instance, echoing some more general theories of creativity, Bashwiner (2018) characterized the composition process as structured into three main stages: a generative stage characterized by the effortless flow of ideas, a transformative stage characterized by craftsmanship and elaboration, and an evaluative stage characterized by a composer's hedonic reaction to the products of the first two stages.

In sum, research has yielded many candidate concepts and cognitive processes that are potentially useful for understanding of the nature of the creative process in music. These varied approaches share a view of music as a form of ill-defined problem solving, in which there is no single 'correct' answer or 'best' solution. To achieve a good-enough solution, composers must make many decisions, organizing and structuring their ideas and behavior to transform nascent ideas into a performable product. Composers' means of structuring their creative problem-solving behavior can be regarded as schemas that reflect their domain-specific knowledge. In line with expertise accounts of creativity (Weisberg, 2006), the composition process itself is often regarded as highly rational (Kozbelt, 2008a), which has strong implications for issues like the extent to which creators could learn to control the creative process and become more creative with experience – questions that have been informed by archival studies of great composers.

Archival Studies of Musical Creativity

Archival studies of classical composers use their outputs and pragmatic assessments of the quality of that output (like recording counts or citations in music history books) to test hypotheses on how, for instance, output changes with age (Simonton, 1997). Psychologists have developed two major perspectives on lifespan creativity: the expertise acquisition view (Weisberg, 2006) and the blind variation and selective retention (BVSR) view (Simonton, 1997, 2011). The two theories make different assumptions and predictions about how creativity unfolds throughout creators' lives. The expertise view emphasizes domain-specific knowledge and logical problem-solving processes and is thus optimistic about creators having some control over their creativity and improving with experience. In contrast, the BVSR perspective emphasizes serendipity and a quantity-drives-quality dynamic, and it has traditionally been more pessimistic about the possibilities of creative control and agewise improvement.

The most direct evidence bearing on these two views comes from empirical studies in which aspects of creators' outputs are quantified. One operationalization is career landmarks: the ages at which individual composers began studying music, composing, wrote their earliest acknowledged masterwork, greatest work, and final masterwork, and stopped composing altogether. Some results on career landmarks support the expertise acquisition perspective, particularly the so-called 'ten-year rule' (Kozbelt, 2008a) mentioned earlier, but others do not. For instance, the very greatest composers began studying and writing music – and masterpieces – earlier, and they wrote their last masterpiece later than their less eminent counterparts (Simonton, 1991). Some similar trends apply to

'one-hit wonder' composers (those whose reputations are based on one outstanding work), versus those who produced multiple great works (Kozbelt, 2008b). Such findings suggest the acquisition of expertise and its translation into creative productivity can be strongly modulated by individual differences in creative potential or talent.

Many findings on career landmarks can be understood via the BVSR account (Simonton, 1997, 2011). This theory takes individual differences in creative potential as a starting point and models typical age-wise output in a way consistent with observed results: productivity starts low, rapidly climbs, peaks around age 40, and gradually declines. Intriguingly, the classic BVSR view (Simonton, 1997) explicitly posited a general inability of creators to control the creative process or systematically improve with age. However, subsequent research has revised this view somewhat. For instance, extensive studies of thousands of works by dozens of great composers (Kozbelt, 2008a, 2011) showed significant long-term improvements in several indices of creativity over the course of composers' careers, inconsistent with the classic BVSR model. In these studies, substantial individual differences in trajectories were also notable. Specifically, composers who wrote their best work later in their careers showed stronger age-wise improvements in creativity and weaker quantity-drives-quality dynamics than did early-peaking composers (see Longevity).

The pervasiveness of such individual differences suggests that any sort of one-size-fits-all view of creativity may be misguided. An alternative is to prioritize inter-creator variability, which may be organized into typological categories. One prominent example is Galenson's (2006) framework of 'finders' and 'seekers.' Kozbelt (2012) applied Galenson's typology to music, coupling quantitative findings on variability in composers' career trajectories with qualitative accounts of their compositional concerns and processes. In brief, 'seekers,' who show longitudinal improvement and late career peaks, work in traditional forms highlighting craftsmanship and the development of musical ideas, incrementally and deliberately seek longitudinal improvement within the context of tradition, and distrust preconceived theories of composition. In contrast, 'finders,' who often produce their best-known work early in their careers, prioritize novel ideas, pioneer new musical forms, can articulate their compositional goals via clear-cut theoretical criteria, and show great certainty while creating and confidence in their self-evaluations. Thus, there appear to be many pathways to greatness in music, with variability at one level of analysis (like the creative process) predicting outcomes at a very different level (like career trajectories).

A final aspect of archival research relevant to musical creativity concerns composers' ultimate reputations, operationalized by differential space allotment in music history books. Murray (2003) has amply demonstrated high concordance among varied sources in classical music (and other domains) and has invariably found a strongly positively skewed distribution of achievement, with a few supremely eminent figures significantly outdistancing their nearest competitors and the great mass of contributors at the bottom end of the distribution. Such findings raise the question of how social judgments of the relative importance of different creators and their contributions are formed – a theme taken up below.

Neuroscience Studies of Musical Creativity

In the last several decades, advances in imaging technology have led to a revolution in our understanding of the brain – even on issues as complex as musical creativity (see Neuroscience fMRI). What do such studies tell us? Bashwiner (2018) surveyed some twenty or so neuroscience studies in which participants engaged in musical composition or musical improvisation. While extant research involves a diverse array of neuroimaging methods, tasks, participants, musical styles, and degrees of ecological validity, several overarching consistencies are evident. These include: the frequent implication of motor control regions, especially those used for motor planning and sequencing like the premotor cortex and supplemental motor area; the sometime involvement of non-primary auditory regions; inconsistent involvement of regions of the default mode network, which is associated with internally directed focus and mind-wandering (see Neuroscience Default Network); inconsistent involvement of dorsolateral prefrontal cortex, an area implicated in higher-order cognitive faculties like executive function and cognitive control; and relatively consistent involvement of limbic and paralimbic structures, which are typically involved in emotion processing.

While neuroscience research on musical creativity remains in its infancy, these tentative patterns suggest some routes of future exploration. Deeper insights connecting these brain-based findings with broader questions about the nature of composition and improvisation are likely to arise through a multi-pronged approach. Combining physiological responses, like skin conductance, with better laboratory-based metrics of creativity across a range of musical skill levels and tasks, would likely be a useful direction. Bashwiner (2018) has also contributed theoretical ideas linking composers' reports of their composition process to neuropsychological models of dreaming and so-called bizarre cognition.

Socio-cultural Aspects of Musical Creativity

Psychological studies of the creative process – whether observational, archival, or neuroscientific – are sometimes critiqued on the grounds that they over-emphasize the role of the individual creator, at the expense of communal and collaborative aspects of music, which are extremely common. These include purely musical group efforts like the Lennon-McCartney songwriting partnership, the interdisciplinary interaction of composers with creators in allied domains like film or dance or advertising, improvisation in jazz ensembles, the use of music in group ceremonies, and so on. Along these lines, even some recent neuroscience accounts emphasize music's ability to foster an interpersonal sense of being together in time that is rooted in neural processes of imitation, intention, action, and emotion. Some evolutionary accounts likewise highlight music's ability to promote and reinforce social bonds.

In recent years researchers have paid increasing attention to these issues that transcend individual creators. Fully understanding the nature of creativity in music requires moving beyond domain-specific psychological characterizations of acts of musical

creativity and moving toward the social reception of creative products. This complex, multi-disciplinary topic is replete with unanswered questions and can only be touched on here (see Systems).

The social dynamics of musical creation and appreciation have been much debated by scholars interested in socio-cultural issues. These include how aesthetic choices may reinforce class distinctions, how the social context and situated cultural practice of creative music-making operates, how the plurality of contemporary approaches to music-making works, and how collaborative aspects of musical creativity function. Among these matters, improvisation may be the most underserved specific issue. Oddly, improvisation is simultaneously the most widely practiced musical activity and the least acknowledged and understood – a remark that has long been true, despite growing scholarly interest in the nature of creative collaboration.

Future Directions and Implications

The study of musical creativity is a rich and vibrant scientific enterprise. As this article shows, considerable progress has been made in conceptualizing key issues and in devising theoretical and empirical approaches to understanding them. Much current research benefits from a convergence of multiple methodologies. Future research should continue to pool the many methods now available, coupled with sophisticated computer-based tools to analyze large corpuses of music in order to test well-defined hypotheses. Such approaches have great potential for answering evolutionary, trans-historical, and cross-cultural questions. Together with a rich understanding of the creative process, these remain central in considering the very nature of the domain of music as a fundamental arena for human creativity.

Many unanswered questions about the nature of musical creativity have particular resonance in the contemporary world. Part of this research program is simply understanding how musical creativity unfolds in a pluralistic, resource-rich, highly interconnected, globalizing culture with numerous stylistic niches available for the expression of musical creativity. Anyone with modern technology can access and assess the tremendous variety of musical styles produced by our species. In previous epochs, this kind of broad comparison was simply impossible; facing this reality raises fundamental questions about the nature of human musical creativity. For instance: What is more impressive, the apparent variability in musical styles or the fact that so many of these styles share basic common features? How does the answer to that question inform how we should think about the human capacity for musical creativity, more broadly? Can musical styles and preferences be arbitrarily modulated by cultural convention blank-slate style, or does the evolved structure of the mind constrain our capacity to create and appreciate certain kinds of music? What are the mechanisms by which changes in musical styles or preferences might unfold over time?

As noted earlier, the complex interplay between these various forces – productive and receptive, biological versus cultural, domain-general versus domain-specific – introduces an inherent long-term tension into the dynamics of high-level musical creativity. Considering music as a fundamental domain of mind suggests that many aspects of human musicality may be inborn. Even quite young infants show sensitivity to many aspects of music and evince systematic musical preferences, and music has been characterized as a natural creative process in the human mind that facilitates expression and communication.

Similarly, numerous regularities are evident across human music worldwide. These include the importance of the octave and other simple pitch ratios like the perfect fifth, categorizing the octave into tones, unequal interval sizes in scales and the tonal hierarchies resulting from them, principles of grouping and meter, and the importance of melodic contour (Justus and Hutsler, 2005). Purves (2017) has suggested that such commonalities reveal that music derives from an evolved capacity to understand spoken language, which is almost unique among ambient environmental sounds in its predominantly tonal quality. The tonal qualities of speech are echoed in regularities across musical styles and tonal systems around the world.

Against this backdrop of evolved preferences, music itself evolves. Quantitative archival studies of melodic originality in the classical repertoire show that melodies tend to become statistically more unusual over time (Simonton, 1994). Moreover, beyond just the note-to-note structure of melodies, numerous other aspects of music have likewise changed over time: in rhythmic and formal patterns, the complexity of counterpoint and instrumentation, relative consonance or dissonance of harmony, level of detail in prescribing aspects of performance, the introduction of multiple styles within a single work, blending of elements from different musical traditions, and so on. These trends have substantial implications for the cultural sustainability of creativity when the imperative for novelty begins to run against the grain of evolutionarily canalized aesthetic preference. Indeed, ambitious creators' rampant pursuit of novelty may greatly outstrip audiences' capacity to appreciate their productions. How this all ultimately plays out is, of course, a mystery.

In any case, human musical creativity continues to emerge from a complex dynamic. Within this dynamic, on one hand, people are constrained due to their evolved biological capacity for musicality, the historical record of musical styles, and larger socio-cultural factors impacting musical creation and consumption. On the other hand, individuals have an equally human capacity for creative innovation. The co-evolution of these factors and faculties promises to keep the study of musical creativity an active area of scholarly and scientific research for the foreseeable future.

Introduction

This entry discusses gray matter structural studies on brain imaging to evaluate creativity as measured by divergent thinking (DT) and other laboratory measurements. In humans, psychometric intelligence is strongly associated with various quantitative structural measures and microstructural properties of gray matter, as shown by structural magnetic resonance imaging (MRI) techniques as described below. In recent years, structural neuroimaging studies have used similar methods to identify correlations between the properties of brain structures and measures of individual creativity to tap the neural sources of individual creativity. In this chapter, these studies are reviewed and their methodologies and implications are described.

Three representative psychological measures for creativity, DT, convergent thinking, and self-report questionnaires are primarily used in the neuroimaging field of the structural bases of individual creativity as described below. However, there are additional approaches including others' evaluations, eminence of the accomplishment, and realistic problem solving.

A brief review of methodological approaches for studying gray matter structures in the brain will be discussed along with the findings.

Creativity Measures

Divergent thinking

In laboratories, creativity is most often measured using divergent thinking tests. For measurement of verbal divergent thinking, the subject is instructed to generate as many ideas as possible in response to a certain question. In figural divergent thinking tests, the subject is presented a picture and is required to respond using their variations of drawing to certain questions and items. Divergent thinking is proposed to be a key aspect of creativity. DT scores are more strongly associated with creative achievement than psychometric intelligence (for a meta-analysis, see [Kim, 2008](#)).

Convergent thinking

Alternatively, creative thinking can be measured by convergent thinking tasks. In such tasks, participants are required to produce a single appropriate answer to a close-ended problem (i.e. a problem that has only one solution). One representative convergent thinking task is the Remote Associates Test. This test aims to assess the ability to identify relationships among remote ideas. In the

task, three seemingly unrelated cue words are presented and the subject is required to provide the fourth word associated with all three words. The test findings showed that creative subjects have higher associative fluency as well as more unusual and flexible associations in these tasks.

Self-Report Questionnaires

Self-report questionnaires can also be used to assess creative achievement or creative activity. One widely used measure is the Creative Achievement Questionnaire (CAQ), which assesses individuals' creative achievements through self-reported information. The CAQ includes items assessing achievement in 10 specific domains, including the visual arts, music, creative writing, dance, drama, architecture, humor, scientific discovery, scientific discovery, invention, and culinary.

Structural Analysis of Gray Matter

There are two well-used approaches to assess gray matter structures: one involves various types of quantitative measurements that are derived from high-resolution structural images and the second method involves the so-called "mean diffusivity", which is measured using "diffusion tensor imaging".

To evaluate associations between individual creativity measures and structural and quantitative measurements of gray matter, high resolution structural images are used to measure (1) regional gray matter volume, (2) regional gray matter density, (3) cortical thickness and (4) surface area. Analyses of regional gray matter volume and regional gray matter density usually employ voxel-based morphometry.

Voxel-based morphometry is a structural processing technique using a brain MRI that involves voxel-wise analysis of correlation between regional gray matter volume or regional white matter density (the probability of the existence of gray matter tissue in a certain area compared with other tissues) and any other factor of interest, such as age or cognitive function (Ashburner and Friston, 2000). In voxel-based morphometry preprocessing, individual structural images are segmented into gray matter, white matter, and cerebrospinal fluid. In voxel-based morphometry, the images from all individuals are registered (fitted) to the same template. In the case of regional gray matter volume, during the registration step, the volumes of the original brain images, before registration to the template, are preserved in the signal strength of the resulting images. For statistical analyses, brain images were divided into small voxels across the entire brain; moreover, regional gray matter volume and density were compared across participants at every voxel. Subsequently, correlations between regional gray matter volume and variables of interest (in the present case, psychological creativity) in each voxel of the brain can be analyzed. Although the exact physiological mechanisms remain unclear, brain volumes are shown to correlate well with representative cognitive functions such as intelligence in normal participants.

Cortical thickness is another quantitative measure of gray matter structures. As shown in Fig. 1 and our previous study (Takeuchi and Kawashima, 2018), cortical thickness is defined as the distance between the white matter and pial surfaces (a surface represents the boundary between gray matter and cerebrospinal fluid). Another measure termed "surface area" is defined as the total area of the white matter surface. The cortical volume of gray matter can be calculated as the product of the cortical thickness and surface area.

These kinds of gray matter quantitative measures are suggested to reflect the number and size of neurons and glial cells, the level of synaptic bulk, and the number of neurites that exist in gray matter. However, this notion must be confirmed by experimental studies. Also, cortical thickness and surface area are shown to have different structural properties and different correlates, each of which can provide unique information.

Structural Analysis of Gray matter—mean diffusivity

As summarized in our review (Takeuchi and Kawashima, 2018), mean diffusivity measures by diffusion tensor imaging can be used to assess the microstructural properties of various brain regions. Diffusion tensor imaging is a method that is sensitive to

Figure 1 Schema of gray matter structural measurements. (Two left panels) Schema of gray matter, white matter, cortical thickness, white matter surface, and pial surface. (Right panel) Schema of mean diffusivity.

the direction of and distance traveled by free water molecules (diffusion) within tissues. The movement of free water molecules can be impeded by tissue microstructures and therefore diffusion tensor imaging can measure the properties of individual tissue microstructures. Mean diffusivity reflects the overall distance traveled by the free-moving water molecules independent of directionality. In a normal brain, lower mean diffusivity represents less free water movement, which is caused by more tissue and cellular structures of various types. These tissue structures may include capillaries, synapses, spines, and macromolecular proteins; properties of myelin, membrane, and axons; the shape of neurons or glia; and enhanced tissue organization. In particular, individual differences in mean diffusivity in the dopaminergic system are associated with various conditions characterized by altered dopaminergic functions.

Associations Between Creativity Measured by DT and Quantitative Measures of Gray Matter

The results of 20 studies of the associations between quantitative measures of gray matter (gray matter volume/density and cortical thickness) and creativity measures are summarized in Fig. 2. We previously summarized the findings of nine studies of associations between creativity measured by DT and quantitative measures of gray matter, and concluded that such findings were mostly not replicated and the associations between creativity measured by DT and quantitative measures of gray matter were elusive (Takeuchi

Figure 2 Gray matter correlations with creativity indices. Notes: DT = Divergent thinking. Circles (○) represent findings of GM volume. Squares (□) represent findings of gray matter density. Diamonds (◆) represent findings of cortical thickness. Pulses (+) represent findings of surface area. Orange color within shapes represents a positive correlation, whereas light blue color represents a negative correlation. Marks with red peripheries involved statistical methods that have not been shown to be improper, whereas marks with blue peripheries involved cluster size tests, which have been shown to fail to control the false positive rates in most conditions; however, the conditions of the study seem to fall within conditions under which the test may appropriately control false positive rates (Silver et al., 2012). Marks with blue peripheries involved statistical methods shown to be inappropriate in recent years or statistical approaches that do not correct for multiple comparisons across the whole brain from the beginning, such as region of interest approaches. The width of the marks represents the sample size of each study. The number in the figure is the study number listed in Table 1. "O" represents findings of originality.

and Kawashima, 2018). In this entry, we separated creativity measures into verbal DT, visuospatial DT, measures of convergent creative thinking, and other creativity measures.

As stated, the findings of each study have mostly not been replicated in subsequent studies in this summary of 20 studies. For the four types of creativity measures, the areas of significant associations between creativity measures and gray matter quantitative measures were distributed all over the brain. Although we did not put the information in a figure (as there were no significant results), we previously analyzed the associations between verbal creativity measured by DT and regional gray matter volume in 1336 young adults; using robust statistics, we found no significant associations (Takeuchi and Kawashima, 2019).

We previously suggested possibilities why consistent findings were not seen in studies of the associations between creativity measured by DT and brain quantitative imaging measures (Takeuchi and Kawashima, 2019):

- A Low effect size and widespread results. In neuroimaging studies of associations between individual cognitive differences and quantitative brain measures using several hundred subjects and robust statistics, findings tended to be seen in widespread areas, and single regions did not show mid to large effect sizes ($r > 0.2$).
- B Antinomic nature of creative measures. Creative measures are known to have complex antinomic psychological properties. For example, on one hand, the DT score is associated with greater processing speed, which is associated with greater brain volume. On the other hand, the DT score is also associated with a tendency toward psychosis, which is associated with lower gray matter volume in widespread areas. These measures indicate that certain psychological components of DT tend to associate with higher gray matter volumes, whereas other psychological components of DT tend to be linked with lower gray matter volumes. These complex opposing natures of DT may cancel each other out, and as a result, the associations between creativity measured by DT and gray matter quantitative measures may be tenuous.
- C Complex nature of gray matter quantitative measures. Gray matter volume is, in our opinion, a complex measure. Similar to body volume, multiple factors can increase gray matter volume. For example, use-dependent increases and decreases of gray matter volume following cognitive training have been reported. After adolescence, cortical thinning occurs in many areas of the brain in parallel with cognitive development until at least young adulthood. Advanced cortical thinning is associated with preferable development of cognition. However, neural atrophy is known to decrease gray matter volume. These complex relationships of gray matter quantitative measures may weaken the associations between creative measures and gray matter.
- D Sex differences in neural correlates of DT. Using a large sample size and robust statistics, we previously showed that there are sex differences in the associations between creativity measured by DT and functional and structural connectivity measures. These may exist in parallel with sex differences in psychological correlates of creativity measured by DT. For example, one study reported that the association between creativity and psychopathology differs between sexes, with a stronger positive association seen among men. Several studies have suggested differences in the associations between creativity measures and gray matter quantitative measures in men and women, as well as in healthy controls and patients with bipolar disorder. The differential patterns of associations between creativity measures and gray matter quantitative measures in different groups may weaken associations in analyses involving samples that include various different subject groups.
- E Low statistical power. As there are numerous areas of the brain to be analyzed in the whole brain imaging analyses, the burden for correction of multiple comparisons in statistical tests is tough. Therefore, it generally takes more resources to gather brain imaging data compared with psychological data. As a result, there are likely to be many studies that are lacking in statistical power (sample size) in the field.
- F Inappropriate statistical methods for correction of multiple comparisons. Probably due to the tough burden for correction of multiple comparisons in statistical tests of the vast number of brain areas, several types of “cluster size tests” have been developed and widely used. These tests essentially consider the spatial extent (the size of the areas where the statistical effects are observed at certain thresholds) and strength of the effect when correcting for multiple comparisons. However, in recent years, studies have shown that such tests are not properly controlling false positives in brain imaging, or that the conditions under which they work are very limited. Another statistical method called the (voxel-based) false positive rate may also have problems when applied in brain imaging studies, but has widely been used. We outlined studies that have used such methods in Table 1 and Fig. 2. Studies marked with red-colored peripheries used statistical methods that have not been shown to be improper. Studies marked in yellow used cluster size tests that have been shown to fail to control false positive rates under most conditions, but the conditions of the study seem to fall within the conditions where the test may appropriately control false positive rates (Silver et al., 2012). Most studies used statistical methods shown to be inappropriate in recent years or statistical approaches that do not try to correct multiple comparisons across the whole brain from the beginning, such as region of interest (ROI) approaches (marked with blue peripheries). The use of inappropriate or lenient statistical methods may lead to divergent findings in this field of study.
- G Publication bias or high degree of freedom in methods. Other problems that are common to science are also worth noting. One problem is publication bias, as researchers tend not to publish negative findings and will in fact have difficulty publishing negative findings. Therefore, researchers may tend to report false positive findings instead of true negative findings. We believe these tendencies are particularly common in neuroimaging due to the stringent corrections for multiple comparisons when studying the whole brain. Negative findings are far from null effects and, therefore, it is usually difficult to say something from negative findings. A high degree of freedom in methodologies may also be a source of divergent findings in the field. In the case

^aNon-stationary cluster size was shown to be mostly invalid; however, under conditions of high smoothness of imaging data, more stringent cluster determining voxel-level threshold, and higher degrees of freedom, it tends to work (Silver et al., 2012).

^bThe interaction effects are seemingly driven by effects in the non-artist group.

of associations between neuroimaging measures and creativity measures, there are many degrees of freedom in how we preprocess obtained structural images and what measures (gray matter density, gray matter volume, cortical thickness) we use. Further, in the case of DT, instructions regarding the focus on quality, quantity, and scoring methods are known to affect the properties of DT measures. These factors may result in diverse findings.

Among such findings, there are several points worth noting. First, among the divergent findings, posterior midline structures—including the precuneus/cuneus and posterior cingulate cortex—tend to have significant findings (although the significant correlations are positive correlations in some studies, whereas they are negative correlations in other studies). These areas gather information from a wide range of brain regions and contribute to visual and mental imagery, self-related mental representations, and episodic memory retrieval. All of these cognitive processes likely contribute to creativity. The associations between DT performance and brain structures from the areas involved in visual and mental imagery and episodic memory may be consistent with the psychological findings because even verbal DT is positively associated with visual mental imagery ability.

Furthermore, five studies reported that visuospatial creativity measured by DT and artistic creative achievement measured by questionnaires showed negative correlations with gray matter quantitative index in regions of the anterior cingulate cortex (Fig. 2). Although the various subregions of the anterior cingulate cortex have many function, one important role of this area relevant to creativity is focused attention (Gasquoin, 2013).

Various studies have suggested that creativity is associated with leaky attention or unfocused attention. For example, psychological studies have shown that creative subjects are insufficient in dealing with a selective attention task, bad at ignoring irrelevant external stimuli, and bad at suppressing unattended information processing (Necka, 1999). Therefore, associations with reduced quantitative measures of gray matter and visuospatial or artistic creative measures (if any) may be relevant to this area's role in attention. Further, while it is known that vulnerability to psychosis is associated with creativity, this vulnerability is also associated with reduction of gray matter quantitative measures. Therefore, the psychological profile of creative subjects may account for the observed associations between gray matter and creativity measures in this area.

Furthermore, a handful of studies showed associations between creativity and quantitative gray matter in areas in the lateral prefrontal cortex. For example, the writing practice in writers and controls was shown to be positively correlated with regional gray matter volume in the rostrolateral prefrontal cortex using robust statistics (known as voxel-level family-wise error correction) (Neumann et al., 2018) (red circle in Fig. 2). The rostrolateral prefrontal cortex is involved in evaluation of internally generated information, as well as successful task completion that requires problem solving in two or more domains and successful coordination of two or more cognitive operations. In addition, this area is activated during creative story generation (Howard-Jones et al., 2005). These cognitive processes subserved by the rostrolateral prefrontal cortex may thus contribute to creativity.

On the other hand, everyday creative behaviors (engagement in literary, performing, and visual arts and crafts) were shown to be positively correlated with regional gray matter volume in the right premotor cortex using a robust correction for multiple comparisons method called voxel-level family-wise error correction (Zhu et al., 2016) (red circle in Fig. 2). This right premotor cortex is involved in planning and selecting novel actions, as well as higher order cognitive processes including a number of verbal and visuospatial creative activities.

Other regions of the lateral prefrontal cortices are suggested to play important unique roles in creativity. For example, the dorsolateral prefrontal cortex is involved in cognitive abilities, such as working memory, sustained attention, cognitive flexibility, and fluency in the generation of ideas and judgments of appropriateness, which contribute to creativity. The ventrolateral prefrontal cortex plays a key role in internal speech (a person's inner voice which provides a continuous verbal monologue of thoughts) and lesions in this area lead to a deficit in speech production, which in turn leads to reduced linguistic output (Flaherty, 2005). This condition is suggested to be similar to creative block—particularly writer's block.

However, studies on artistic development in patients with frontotemporal dementia suggest that language may inhibit certain types of visual creativity (Mell et al., 2003). Transcranial direct current stimulation (tDCS) studies have shown that inhibitory stimulation of the left ventrolateral prefrontal cortex facilitates generation of creative responses as well as creativity measured by DT (Maysseless and Shamay-Tsoory, 2015). Therefore, the associations between the ventrolateral prefrontal cortex and creativity appear to be complex and inconclusive.

Mean Diffusivity Findings

We conducted two studies of mean diffusivity related to verbal creativity measured by DT. In one study, we showed that the major personality traits exhibiting robust associations with creativity measured by DT showed strong correlations with mean diffusivity in the bilateral pallidum. Further, we showed that verbal creativity measured by DT is indirectly associated with mean diffusivity in the pallidum via the associations of these personality traits.

Specifically, lower mean diffusivity in the right pallidum was associated with greater novelty seeking, lower harm avoidance (personality characterized by excessive worrying, pessimism, shyness, and being fearful, doubtful, and easily fatigued), greater self-directedness (personality trait of self-determination, i.e., the ability to regulate and adapt behavior to the demands of a situation to achieve personally selected goals and values), and greater self-transcendence, which are in turn associated with greater verbal creativity measured by DT. Furthermore, lower mean diffusivity in the left pallidum was associated with greater

Figure 3 Schema of the models of associations among creativity measured by DT, personality, and mean diffusivity in the bilateral globus pallidus, which was suggested in our previous study (Takeuchi et al., 2015). Notes: DT = Divergent thinking. Red arrows indicate positive effects, whereas blue arrows indicate negative effects. Dotted lines indicate cases wherein the model with the existence of the path fit the model best, but the path failed to reach significance. Bidirectional arrows indicate models in which both directions fit the data equally.

persistence (personality characterized by perseverance despite frustration and fatigue, as well as a tendency toward a persistent pursuit of desired goals), which in turn is associated with greater verbal creativity measured by DT (Fig. 3) (Takeuchi and Kawashima, 2018).

When an affective state is finely divided, unlike other affective states, the greater motivational state (state of vigor) is also associated with lower mean diffusivity in the right globus pallidus (shown using robust statistics), as well as verbal creativity measured by DT. This greater motivational state was also found to be associated with greater novelty seeking, lower harm avoidance, greater self-directedness, greater self-transcendence, and greater persistence. In another study, we showed that mean diffusivity of the right globus pallidus was negatively correlated with extraversion (, while greater extraversion was positively associated with greater divergent thinking abilities. These findings suggest robust associations between mean diffusivity of the globus pallidus and traits and states associated with creativity measured by DT. Takeuchi and Kawashima, 2018).

The globus pallidus and adjacent areas are suggested to play a key role in motivation. It is possible that increased tissue in the globus pallidus may be associated with greater motivation, and this association could help explain the associations between several traits that underlie creativity measured by DT and mean diffusivity in the globus pallidus.

As summarized similarly previously, physiologically, the globus pallidus receives dopaminergic input from the substantia nigra and is related to dopaminergic function. A wide range of psychological studies support associations between creativity measured by DT or other creativity measures and dopaminergic function. For example, there are associations between creativity measured by DT and traits related to dopaminergic function, such as schizotypy, novelty seeking, and extraversion, as described above. Interestingly, the pathological condition of dopaminergic dysfunction leads to loss of creativity, and artistic creativity in such pathology is recovered by use of dopamine agonists, while dopamine antagonists are known to suppress creativity.

Creativity is also associated with greater motivation, which is associated with dopaminergic functions. Based on our previous review of the mean diffusivity literature, we concluded that mean diffusivity in the dopaminergic system is associated with a wide range of psychological, pharmacological, and pathological conditions related to functional alterations in the dopaminergic system. Therefore, the observed associations between mean diffusivity of the globus pallidus and a wide range of psychological traits and states associated with creativity measured by DT may be partly behind the traditional idea that creativity and dopaminergic function are linked.

Overall Discussion

Overall, the associations between creative measures and quantitative measures of gray matter are divergent and elusive at best. Particularly, we failed to find significant associations between regional gray matter volume and verbal creativity measured by DT using a large sample size and robust statistical methods. We cited possible reasons for this phenomenon. However, potential associations involving posterior midline structures, such as the precuneus and posterior cingulate cortex, anterior cingulate cortex, and areas in the lateral prefrontal cortex, are suggested.

Using a large sample size, we found consistent associations of mean diffusivity of the globus pallidus with traits and states associated with creativity measured by DT, and suggested the importance of motivation for these associations. We suggest that these findings might underlie the suggested link between dopaminergic function and creativity.

By reviewing studies of associations between individual cognitive differences and neuroimaging measures in young adults, we concluded that the associations are generally very weak. Larger sample sizes and robust statistical methods are needed to generate more reliable findings in the field.

The Role of the Cerebellum in Thought and Creativity: A Monumental Neuroscience Breakthrough

Three decades ago, leading cerebellum researchers proposed that just as the cerebellum contributes to the refinement and automaticity of motor skills, the cerebellum's connections to the prefrontal cortex and Broca's language areas (areas 44 & 45) contribute to planning and language. In essence, they proposed that, 'operating below the level of conscious awareness,' the cerebellum contributed to increased levels of thought in the following way:

Cerebellar connections to Broca's area may not only increase the speed and skill of speaking but also confer other benefits on humans. Because Broca's area communicates with other association areas in the cerebral cortex, the cerebellar signals to Broca's area could increase the speed and skill of such intracortical communication. These communications between cortical association areas are said to comprise the language of thought (Luria, 1980). Therefore, the processes of rationale thought may be performed with increased speed and skill in the human brain as a consequence of its enlarged cerebro-cerebellar connections. (1989, 1006)

In the time since the publication of this breakthrough research, it has been further established that the cerebellum indeed does participate greatly in language and thought.

The Cerebellum Plays a Prominent Role (Perhaps a Predominant Role) in Driving People to Be Creative

The language and thought functions of the cerebellum described in the above quote evolved primarily during the last million years. Because the cerebellum has the key role in refining *all* of our specific skills, including mental skills, neuroscience researchers have argued that part of this refinement process by the cerebellum is to produce new and useful ideas and technology. In other words, the cerebellum drives people to be creative. Moreover, it has been proposed that it was the evolution of the new language and thought functions of the cerebellum that was largely responsible for driving the advanced stone-tool technology and culture of *Homo sapiens* into existence.

The Neural Mechanisms by Which the Cerebro-Cerebellar System Produces Potentially New and Useful Ideas, Objects, Technology and the Arts

It is now established that through the 'repetition' of motor skills, thoughts and related emotions, the cerebellum 'optimizes' the usefulness, speed, and appropriateness of 'internal models' it learns and constantly sends them back to the cerebral cortex toward the increasingly efficient achievement of goals. [Cerebellar internal models are called internal models, because they are neural representations (models) of processes going inside the rest of the brain.] For example, a basketball player repeatedly shoots baskets and through this practice soon becomes very skilled at making baskets from a variety of locations. The basketball player may even

develop innovative and creative signature moves that result in making baskets in perhaps situations of unheard of difficulty. As a more thought- and language-based example, teachers and professors, after repeating their lectures many times, often no longer need their notes and can give their lessons in many innovative and creative ways on the fly, much as a well-practiced musician can easily carry on conversations or improvise in new directions during the playing of a musical piece. Dedicated practice among even musical child prodigies relies on cerebro-cerebellar loops to reach errorless levels of performance including improvisation at a very early age, usually under age 10. [Vandervert and Vandervert-Weathers \(2013\)](#) described how prototyping in the classroom can take advantage of cerebro-cerebellar processes to produce higher levels of practical innovation and creativity, for example, in prototyping that leads to new technology. In all of these examples, the cerebellum silently (below the level of conscious awareness) learns highly efficient internal models of repetitive ideas and activities.

Four Ways the Cerebellum Has Been Shown to Drive Creative Optimization

It is now thought that, through socialization, the cerebellum learns to automate and optimize repetitive, routine patterns of thought and behavior that are constantly going on around us; thus, we unconsciously (for the most part) participate in culture (see Relevant Websites). However, the cerebellum can also be shown to be prominent in the learning of not only everyday skills but additional optimizations that lead to the production of creative ideas. The cerebellum accomplishes this production of new and useful ideas in at least four ways. First, the cerebellum orchestrates the 'decomposition' of motor and mental skills that have been learned in the cerebral cortex so that they then may be sent back to the cerebral cortex in new forms that help achieve new goals. Second, through constant 'error-correction' the cerebellum optimizes motor and mental skills that have been re-organized (blended) in the cerebral cortex; although these new blends originate in the cerebral cortex, this cerebellar optimization of these blends may bring these skills to levels where they result in new and useful ways of doing things and/or thinking about things. Third, the cerebellum learns its optimizations below the level of conscious awareness. Fourth, therefore, because new optimizations are learned unconsciously, when wholly new blends (new ideas) are sent to the cerebral cortex, they may be experienced as insight or 'intuition.' This overall, four-part process may be referred to as cerebellum-driven 'creative optimization.'

Cerebellum-Driven Unconscious Optimization Makes New Ideas Seem to Come From Nowhere

Cerebellum researchers have convincingly argued that, taken together, the four above-described cerebellum-driven processes can explain the common experience wherein one may not know how they learned a new signature move in sports, or how they came to stumble upon an insight that led to a creative idea, new artistic expression, or marketable high-tech product. That is, because such cerebellum-driven creative experiences and new, unique skills are the result of optimization processes which operate below the level of conscious awareness, they seem to our conscious experience to suddenly come out of nowhere!

The 'Sequential' Computations of the Cerebellum Both Optimize and Predict Our Ability to Achieve Future Goals, Including Imaginary Goals

How, exactly, does the cerebellum participate in creating new and useful ideas, art, and technology? What is the nature of its magic? Two independently working research teams zeroed in on the nature of the computations that lead the cerebellum to predict and anticipate what is coming next during all problem solving. This work revealed the universal neural platform of unlimited cause-and-effect analysis leading to new, progressively more refined solutions to problems. A leading team of cerebellum researchers referred to these computations, called sequence detection, as the cerebellum's 'trick for predicting the future.'

The first team in proposing this view, [Akshoomoff et al. \(1997\)](#), concluded that thought and motor control (among other processes they list) are unconsciously learned in the cerebellum through the detection of ordered sequences going on in all movement and thought:

The cerebellum is a master computational system that adjusts responsiveness [toward optimization] in a variety of networks to obtain a prescribed goal [including imaginary goals related to better ways of doing things]. These networks include those thought to be involved in declarative memory, working memory, attention, arousal, affect, language, speech [Broca's area], homeostasis, and sensory modulation as well as motor control. This may require the cerebellum to implement a succession of precisely timed and selected changes in the pattern or level of neural activity in these diverse networks. We hypothesized that the cerebellum does this by encoding (learning) temporally ordered sequences of multi-dimensional information about external and internal events (effector, sensory, affective, mental, autonomic), and, as similar sequences of external and internal events unfold, they elicit a readout of the full sequence in advance of the real-time events [this readout is the basis of progressively more detailed cause-and-effect relationships and thus broader and more detailed prediction]. This readout is sent to and alters, in advance [italics added], the state of each motor, sensory, autonomic, attentional, memory, or affective system which, according to the previous learning of this sequence, will soon be actively involved in the current real-time events. So, in contrast to conscious, longer time-scale anticipatory processes mediated by cerebral systems, output of the cerebellum provides moment-to-moment, unconscious, very short time-scale, anticipatory information. (p. 592–593)

This quote simply states that through the detection and predictive encoding of problem-solving sequences, the cerebellum is able to unconsciously predict (anticipate) good and often new solutions to problems before they occur. Vandervert (2018) described how, over repetitions of thought and movement, this sequence detection process in the cerebellum peers deeper and deeper into cause-and-effect relationships.

Predictive information produced by the above-described predictive sequences of information includes constant error-correction (leading to optimization) of future movements and thoughts. This error-correction unconsciously achieves goals at progressively higher levels, and this includes goals related to purely imaginary future accomplishments. For example, in learning to shoot baskets, play the piano, or for a professor to give a university lecture, the sequence detection process notes errors in movements and thoughts and *automatically* modifies them for its next anticipatory response. Recall from earlier in this discussion that, in this process, behavior and thought are constantly being decomposed and re-organized by the cerebro-cerebellar system to more efficiently solve the problem at hand and to solve problems in new ways. Since these cerebellar processes also take place in thought that takes place in working memory, this error-correction toward more efficient problem solving applies to both online, real-time problem solving and cerebellar memory consolidation during sleep. More broadly, this means that when we are thinking about other problems, encountering unrelated experiences, or even sleeping the four mechanisms of cerebellum-driven creative optimization are at work! This exclusive, silent 'cerebellum time' away from a specific problem we have been working on would define and produce, in neural terms, the *incubation* phenomenon (Wallas, 1926) that deems facilitative if not necessary to creativity.

Further Evidence of Cerebellar Prediction Through Sequence Detection

The cerebellum's predictive sequence detection in working memory is more clearly shown by the findings of Leggio and Molinari (2015), the second team of cerebellum researchers to zero in on the nature of the computations of the cerebellum. Their findings led them to the following hypothesis on how, through sequence detection, the cerebellum 'simulates' future states of affairs and higher order mental processes:

According to this hypothesis, the cerebellum detects and simulates repetitive patterns of temporally or spatially structured events [sequence detection], regardless of whether they constitute sensory consequences of one's actions in motor planning, expected sensory stimuli in perceptual prediction, or inferences of higher-order processes (e.g., 'cognitive elaboration' [quotes added] or social cognition). The simulation allows internal models [in the cerebellum] to be created that can be used to make predictions about future events that involve any component, such as the body, other persons, and the environment. (p. 36)

The purpose of including this quote here is twofold. First, it supports Akshoomoff et al. (1997) conclusion that the cerebellum's main job is to optimize the preparation of cognition and movement to meet future circumstances. Second, it strongly supports the contention that silent (unconscious) prediction by the cerebellum applies to the highest levels of 'cognitive elaboration.' (The 'simulation' process mentioned by Leggio and Molinari constitutes the learning of cerebellar internal models.)

It is important to emphasize that while not only are Leggio and Molinari (2015) above findings are completely in agreement with Akshoomoff et al. (1997) earlier findings, but they were arrived at independently and through a different research approach. This fact gives high credibility to both teams' conclusions that the cerebellum is key to producing (in a predictive manner) new, workable solutions to difficult problems, including those involving higher-order processes of cognitive elaboration and social cognition that are commonly associated with innovation and creativity. The final section of this article will return to a description of how cerebellum-based prediction can be related to the unique, high-level creativity (a part of cognitive elaboration) of Albert Einstein.

Perplexing Historical Examples of Extreme Creativity Which Can Be Addressed by the Cerebello-Cerebral Approach

Understanding the Role of the Cerebellum in Einstein's Creativity

Albert Einstein was a keen observer of not only the complex relationship between time and space but of how such new ideas emerged within his own experience, and he often wrote about it. Einstein argued in many of his writings that new ideas in science, including his own, were the result of 'unconscious' processes that give rise to intuition. For example, in a 1949 personal letter to fellow physicist H. L. Gordon,¹ he provided a complete picture that connected the unconscious and intuition, and intuition's relation to previous intellectual experience and their combined relationship to new ideas:

A new idea [a new concept] comes suddenly and in a rather intuitive way. That means it is not reached by conscious logical conclusions. But thinking it through afterwards you can always discover the reasons which have led you unconsciously to your guess and you will find a logical way to justify it. Intuition is nothing but the outcome of accumulated earlier intellectual experience.¹

¹Albert Einstein letter to Dr. H. L. Gordon, May 3, 1949. This is Item 58–217 in the Control Index to the Einstein Archive which may be consulted at Mudd Library, Princeton University.

Vandervert (2015) proposed that Einstein's unconsciously driven intuition was produced when the cerebellum sent its unconscious, newly formed internal models to conscious areas of the cerebral cortex, for example to the prefrontal and parietal areas. The repetitive experience necessary to this cerebellum-driven intuition was noted by Einstein. In his Autobiographical Notes, he recalled how he hit upon the idea of his special theory of relativity only after 10 years of repeated reflection on unsolved scientific problems related to motion.

Seven years later, in a personal letter to his long-time friend Maurice Solovine, he emphasized his point on the necessity of intuition in the creative discovery of new axioms in science. In his explanation, he began with immediate experience (E) and then described a necessary intuitive leap of creative discovery to the axioms (A):

A are the axioms from which we draw consequences. Psychologically the A are based upon the E. There is, however, no logical path from the E to A, but only an intuitive (psychological) connection, which is always subject to revocation.

Einstein (1956), pp. 118–121.

Einstein's above closing comment that intuitive connections are "always subject to revocation" fits findings on cerebellum-driven intuitive leaps which are the result of sequence detection as described earlier in this entry. That is, according to Akshoomoff et al. (1997) and Leggio and Molinari's (2015) findings on cerebellar prediction and anticipation, the cerebellum, operating below the level of conscious awareness, constantly adjusts to new experience in a manner that updates the optimization of prediction and often updates these optimizations in the form of wholly new concepts. It is suggested that this cerebellar production of wholly new ideas is the evolutionary advantage that drove the generation-upon-generation of creativity behind the evolution of stone-tool technologies and of language among the genus *Homo*, particularly *Homo sapiens*.

In his day, it was a puzzle for even Einstein as to how thought processes in the brain might produce intuitive solutions to deep problems, solutions that in his case would dramatically change the face of theoretical physics. However, Einstein's above arguments that new and useful ideas even in theoretical physics come about only through intuition which is (1) based upon the accumulation of experience, but, at the same time, (2) is arrived at unconsciously squares well with the more recently discovered cognitive functions of the cerebellum described here. Specifically, Einstein's analysis comports well with Vandervert's (2003) and (2015) proposal that, operating below the level of conscious awareness, internal models learned through the repetitive accumulation of experience in the cerebellum are sent to the cerebral cortex where they are experienced as sudden, intuitive insights. Such intuitive insights may provide new and useful solutions to problems, arguably the basis of all creativity.

How do such intuitive insights produce new ideas that, as in Einstein's case, can change the face of physics? Vandervert (2018) proposed that since through its optimized error-correction the cerebellum constantly refines both the level of detail and applicability of all cause-and-effect relationships, the cerebro-cerebellar system supports not only all skilled movement and thought but, within that thought, deeper and broader scientific models of the physical universe. And, as Einstein suggested in his above quotes, these new ideas can only be arrived at through unconsciously-driven intuition.

Conclusions

Cerebellar decomposition and blending of concepts and skills take place during unconscious incubation that leads to creativity (Vandervert, 2015).

The cerebellar refinement of cause-and-effect relationships provides an explanation of how unconsciously-driven intuition can reveal new scientifically verifiable laws of nature (Vandervert, 2018).

Cerebellum-driven creativity is the neural mechanism behind both the origin and ongoing relentless advance of culture (Vandervert, 2018).

EEG: Basic Concepts and Measures

Electroencephalography (EEG) is a neuroscience method to measure the electrical activity of the cortex. When larger assemblies of neurons act synchronously, brain potentials with amplitudes of up to several 100 μV can be observed. These brain potentials can be recorded with electrodes placed at the scalp. The EEG is characterized by brain oscillations occurring at specific, preferred frequency ranges, which has led to the discrimination of distinct frequency bands (Klimesch, 2018). Alpha activity refers to EEG oscillations in the range of about 8–13 Hz, beta activity refers to EEG oscillations in the range of about 14–30 Hz, and gamma activity refers to EEG oscillations of about 30–100 Hz (usually around 40 Hz). Slower oscillatory activity is reflected in delta activity (0.5–4 Hz) and theta activity (5–7 Hz). Frequency analysis techniques (e.g. fast Fourier transform) are used to compute the power of specific frequencies or frequency bands in the EEG signal over time. EEG can be measured with very high temporal resolution (e.g., 1000 Hz), whereas spatial resolution is restricted. EEG activity mainly reflects cortical brain activity, and spatial resolution is further limited by the number of electrodes (commonly 20–64) and by the fact that nearby electrodes measure overlapping signals. Yet, source localization techniques can be applied to recover the actual sources of EEG activity within the brain (Koles, 1998).

One common approach in EEG research is the analysis of task-related power (TRP) changes elicited by a cognitive task relative to a pre-task baseline. Increases and decreases in frequency-specific power are referred to as synchronization and desynchronization, respectively. For example, if one observes decreases/increases of alpha power from a pre-task baseline to a task period, then this is called alpha de/synchronization (speaking of events, it is called event-related de/synchronization; ERD/S; Pfurtscheller and Silva, 1999). Brain oscillations can also be used to study functional connectivity across cortical sites. Common measures of brain connectivity include coherence and phase-locking. EEG coherence essentially reflects the correlation between signals from different electrode positions, whereas phase-locking reflects the synchrony of phases between signals independent of their amplitudes. These brain connectivity measures represent indicators of inter-regional coupling, which reflects covariation of brain activation, and potentially indicates causal dynamics between local brain networks.

Another analysis popular approach in EEG research is the analysis of event-related potentials (ERPs). Psychological events elicit a characteristic sequence of positive and negative potential changes within about 1 second after the onset of the event. For instance, the P300 denotes a positive peak of brain potential commonly occurring about 300 ms after event onset. These potentials are very small but can be observed reliably after aggregating EEG signals across many trials. Several ERP components are commonly observed (e.g., P50, N100, P200, P300) and have been related to different sensory, cognitive and motor processes. Studies typically compare effects of experimental conditions on the amplitudes of different ERP components.

How to Study Creativity With EEG

EEG is arguably the first neuroscientific method ever applied to the investigation of creativity, with research going back to the 1970s. To date, about half of the available neuroscience studies on creativity have been carried out with EEG, while the other half predominantly employed Magnetic Resonance Imaging (MRI). EEG assessments are largely unobtrusive as they only require participants to wear an electrode cap, but do not restrict body position and movement as much as other methods (e.g. MRI), which allows to study EEG brain activity across a wide range of creative activities. An analysis of 63 available EEG studies on creativity (Benedek et al., 2019) showed that 54% of studies employed divergent thinking tasks (i.e., idea generation tasks), 21% employed convergent thinking tasks (i.e., creative problem solving requiring one solution), and the remaining 25% employed more realistic, product-based tasks such as musical improvisation and imagined or actual drawing. These rates are

very similar to those observed in behavioral research on creativity, which suggests that creativity tasks that are popular and well-established in behavioral research, frequently get adopted by EEG research.

Studying creativity with EEG still requires certain adaptations to meet the requirements of neurophysiological measurements. Importantly, EEG studies on creativity commonly separate time periods of idea generation and actual response production in order to avoid confounds between brain activation data and motor artifacts. This can be achieved in different ways: One common way is to instruct participants to push a button when they come to a solution and only then express their idea. This method allows for self-paced task performance, while enabling experimenters to carry out a post-hoc separation of ideation and response periods relative to button presses [Fink et al. \(2007\)](#). Another common way is to use fixed ideation and response periods, which implies higher experimental control, but requires to specify reasonable task durations that enable valid performance across all tasks (overly short tasks may fail to yield responses, whereas overly long tasks may result in idling). Finally, few studies have measured EEG during actual creative response production (e.g., musical improvisation). These studies control for artifacts by implementing adequate control conditions and making use of effective artifact correction procedures (a more detailed discussion of methodological considerations in the neuroscientific assessment of creativity is given in [Benedek et al., 2019](#)).

Main Findings of EEG Research on Creativity

Investigations of Oscillatory Brain Activity

EEG alpha activity. Investigations of EEG oscillatory activity in creativity have commonly focused on alpha activity, which is the dominant frequency in the human EEG ([Klimesch, 2012](#)). Early work found that EEG alpha activity was higher during the imagination of a creative story as compared to a later period when a story was elaborated and written down. Similarly, people who were more creative exhibited higher alpha activity than less creative people during various cognitive tasks. These findings suggested that creativity is related to higher alpha activity, which was interpreted as evidence that creativity involved lower cortical arousal ([Martindale, 1999](#)).

The positive relationship between creativity and EEG alpha activity has been replicated across many tasks and designs. Specifically, alpha synchronization was found to be higher during tasks with high vs. low creative task demands (e.g. generating creative object uses vs. generating typical object characteristics). Moreover, the generation of more creative ideas was associated with higher EEG alpha activity than the generation of less creative ideas. Studies looking at individual differences found higher task-related alpha synchronization for more creative people compared to less creative people. Finally, EEG alpha activity was increased by creativity training and cognitive stimulation. Most notably, recent evidence suggests that transcranial alternating current stimulation (tACS) in the alpha frequency range increases creative performance. Together, these findings demonstrate a robust positive relationship between creativity and EEG alpha activity (for reviews, see [Fink and Benedek, 2013, 2014](#)). Creative cognition is particularly characterized by alpha synchronization at frontal cortical sites and in posterior regions of the right hemisphere, and by reduced alpha desynchronization at occipital sites (see [Fig. 1](#)).

The robust relationship between creativity and EEG alpha activity raises the question about the functional role of EEG alpha in creative cognition. First of all, it is notable that EEG alpha activity is not only higher in more creative tasks but was found to actually increase relative to a pre-task baseline. This seemed paradoxical at first, given that the traditional interpretations of alpha activity assumed it reflects states of reduced brain activation or “cortical idling.” Other accounts proposed that EEG alpha reflects active top-down inhibition of task-irrelevant brain regions and related it to states of internally directed attention. In fact, parallel studies of creative cognition with EEG and fMRI showed that increased alpha activity in the EEG relates to increased brain activation as measured by the BOLD response in fMRI, suggesting that alpha synchronization represents states of increased rather than reduced brain activity. Further studies showed that more and less creative tasks actually show similar alpha activity when they are matched for sensory demands, and that alpha activity increases in both tasks when they are carried out with reduced sensory input as during task performance in the mind’s eye. Moreover, alpha activity was generally higher for tasks that were intrinsically independent of sensory stimulation compared to tasks that relied on bottom-up stimulus processing ([Benedek et al., 2011; Benedek et al., 2014](#)).

These findings indicate that the creativity-alpha relationship can be explained by the high internal attention demands involved in creative cognition. Creative thought crucially relies on imagination, which is characterized by self-generated, stimulus-independent thought processes such as the generation of novel mental representations and mental simulations, while disregarding irrelevant sensory input. Alpha activity at frontal and posterior brain sites hence seems to represent a top-down gating mechanism to shield ongoing internally-directed processes (i.e., imagination) from sensory interference. This notion was supported by an fMRI study showing that internal attention during creative thought involves reduced activation of the primary visual cortex, which was mediated by activation of the right inferior parietal cortex – the brain region where alpha activity shows the most robust increases during creative thought ([Benedek et al., 2016](#)). Moreover, idea generation and moments of insight are associated with visual disengagement as evidenced by gaze aversion, increased blinks, and reduced microsaccade activity in eye-tracking research ([Salvi and Bowden, 2016; Walcher et al., 2017](#)). Taken together, EEG alpha activity can be viewed as a sensitive neurophysiological indicator of internally-directed attention, likely reflecting the level of absorption by ongoing imagination processes during creative thought ([Benedek, 2018](#)).

The high temporal resolution of EEG activity has been further exploited in the study of temporal dynamics in creative cognition. For example, investigations of EEG activity over the course of creative problem solving observed transient alpha activity increases at

Figure 1 Task-related changes in EEG alpha power during the generation of creative uses in the Alternative Uses task separately for groups of higher versus lower originality. Blue regions indicate increases in alpha power relative to rest (fixation period). AF: anteriofrontal; F: frontal; FC: frontocentral; CT: centrotemporal; CP: centroparietal; PT: parietotemporal; PO: parietooccipital. Taken from [Fink and Benedek \(2014\)](#). *Neuroscience and Biobehavioral Reviews* 44, 111–123.

right parieto-occipital regions right before participants solved problems by insight compared to solving identical problems by analytical processing. The pre-insight alpha burst was assumed to reflect “transient sensory gating that reduces noise from distracting inputs to facilitate retrieval of the weakly and unconsciously activated solution represented in the right temporal lobe” ([Kounios and Beeman, 2014](#), p. 80). Other research looked at temporal dynamics of alpha activity during extended divergent thinking tasks. Studies reported a U-shaped pattern of alpha activity, characterized by increased alpha activity in the beginning and end of both verbal and figural divergent thinking tasks ([Schwab et al., 2014](#)). Findings replicated in other studies, which further found that functional connectivity between frontal and parietal sites increased with time, but faster so for more creative people. In the light of behavioral evidence, these time effects are thought to reflect different stages during creative idea generation, including an initial stage of recall of ideas from memory, followed by shifts towards more strategic search of novel ideas, and a final stage idea evaluation and elaboration ([Benedek and Jauk, 2018](#)). While these increasingly strategic and goal-directed processes involve higher executive control over time (as indicated by increased functional connectivity with frontal brain areas), the first and final stages may draw more strongly on memory-related demands and hence involve higher internally directed attention (as evidenced by increased alpha activity).

While the vast majority of studies focused on EEG correlates underlying divergent thinking and insight problem solving, there is a growing number of studies looking at EEG activity patterns implicated in more realistic creativity tasks. [Fink et al. \(2017\)](#), for example, investigated EEG alpha activity while participants were engaged in the generation of reappraisals to self-relevant anger-eliciting situations. Participants were required to empathize with pictorially presented anger-eliciting situations and to think of as many different ways as possible to reappraise these situations in a manner that reduces their anger. One interesting finding of that study was that generating reappraisals as compared to conventional creative idea generation (Alternative Uses Task) exhibited larger alpha power increases at frontopolar sites, which could possibly reflect increasing executive processing demands associated with the generation of effective strategies to regulate an ongoing negative emotional state.

In another study, [Fink et al. \(2018\)](#) investigated neurocognitive mechanisms associated with creative solutions in naturalistic soccer decision-making situations. During EEG assessment, hobby to amateur soccer players were presented brief video clips of real soccer scenes, and after the image was frozen, they were asked to imagine themselves as the acting player of the attacking team and to think of an original move that might lead to a goal. Performance of this task generally elicited comparatively strong alpha desynchronization at parietal and occipital sites, indicating high visuospatial processing demands during the processing of the complex soccer scenarios. In addition, more creative task performance in the soccer task was associated with stronger alpha power desynchronization over left (primary motor related) cortical sites, suggesting that individuals who generated more creative moves were more intensively engaged in processes related to motor or movement imagery.

Both the study of creativity in an affective context and the investigation of creative solutions in soccer decision-making situations constitute promising examples of studying creativity related brain activity patterns in a more naturalistic or ecologically valid way. Critically, investigations of creative processes in more naturalistic settings also facilitate testing whether the “core creativity network” identified in classic divergent thinking demands generalizes to other types of creative behavior that involve more real-life demands. In fact, both the study of creative processes in the affective and in the soccer domain yielded EEG brain activity patterns that might be relevant across different creativity domains, but they also support the idea that creativity is not a uniform process and rather involves manifold neurocognitive processes depending on the specific creativity domain (Boccia et al., 2015; Gonen-Yaacovi et al., 2013).

Other EEG frequency bands. A few studies have considered the role of other frequency bands for creative cognition. Notably, Jung-Beeman et al. (2004) observed not only an alpha burst right before subjective insights, but this was followed by increased gamma activity at right temporal brain regions, a hypothesized mechanism for binding information as it emerges into consciousness. In a similar study, moments of insight in verbal puzzles were predicted by posterior beta and anterior gamma oscillations (Sheth et al., 2009). Further evidence for the role of beta activity comes from a neurofeedback training study, which found effects on creative performance after beta neurofeedback but not after alpha neurofeedback (Agnoli et al., 2018). The generation of creative continuations to known proverbs was associated with increased upper beta and gamma activity but no changes in other frequency bands. Finally, diverging from a salient rule during a name generation task was found to be related to widespread decreases of delta activity (Boot et al., 2017). In sum, creativity has been associated to activation differences across all frequency bands, but so far, evidence is most extensive and consistent for EEG alpha activity.

Investigations of Event-Related Brain Potentials (ERP)

Event-related potentials can be observed within 1 second after stimulus onset and hence are typically used to study phenomena related to early stimulus processing. One study presented ideas that were either common, creative, or nonsensical and examined ERP responses to evaluations of their unusualness and appropriateness (Kröger et al., 2013). More unusual ideas (creative or nonsense) elicited a higher N400 (i.e., a negative peak at about 400 ms after stimulus onset), whereas later potentials between 500–900 ms tended to be sensitive to the appropriateness of ideas. Quite similarly, the N400 was most pronounced for the processing of unusual metaphors (creative or nonsense) compared to common ones (Rutter et al., 2012). Other studies found a larger (more negative) N400 when participants were presented a solution they had not found themselves. Moreover, N400 was larger when participants solved logogriphs with unrelated versus related words. These findings are consistent with the notion that N400 indexes semantic violations during processing of meaning, and thus may represent a valuable indicator of subjective novelty during idea evaluation.

The ERP approach was further used as index of cognitive control in individual differences research on creativity. For example, when presenting two brief click noises, the P50 (i.e., positive peak about 50 ms after event onset) is attenuated for the repeated, second click noise; hence, this P50 amplitude can be seen as an index of sensory gating. More effective sensory gating was associated with higher divergent thinking ability but with lower creative achievement. Similarly, a larger N200 component for detection of rare versus frequent targets was associated with higher divergent thinking ability but not with higher creative achievement. These findings provide neurophysiological evidence that divergent thinking ability, but not creative achievement, is related to higher executive control (Zabelina, 2018).

Summary

EEG has been frequently used to study oscillatory brain activity and event-related brain potentials in creative cognition. Despite the large diversity of methods and tasks, several consistent findings can be observed. Creativity has been associated with increased EEG alpha activity especially at posterior regions of the right hemisphere. This alpha synchronization likely reflects the inhibition of task-irrelevant processes, and particularly the suppression of sensory processing in order to maintain sustained internally-directed attention and shield ongoing imagination processes. Moreover, the ERP component N400 has been repeatedly associated with the processing of unusual ideas and moments of insight, suggesting that it serves as an index of subjective novelty during the evaluation stage of creative thought. Limitations of the EEG method include its low spatial resolution, which advises the use of complementary techniques (e.g. source localization) or neuroimaging methods (e.g., MRI) to address questions of topographical localization. Taken together, EEG represents a powerful method for the time-critical investigation of neurophysiological mechanisms underlying creative cognition.

Glossary

Alpha-band activity Neural activity that is often linked with relaxation, disinhibition, internally-focused attention, and some creative states.

Cognitive disinhibition The inability to ignore irrelevant information.

Default mode network The neural network comprised of midline and parietal regions that activate during task-unrelated thinking, such as mind wandering, autobiographical retrieval, and episodic future thinking.

Executive functions Control processes that regulate people's thoughts and behaviors.

Frontoparietal control network The neural network comprised of anterior parietal and lateral prefrontal regions, and is thought to play a role in deliberate attentional control.

Latent inhibition The tendency to screen from conscious awareness previously irrelevant information.

"Leaky attention" Attention that allows "irrelevant" information to be noticed.

Working memory Short-term memory that temporarily holds and manipulates information.

Introduction

There is a long-standing interest in the role of executive functions (EFs) in creativity. Historically EFs were considered to be less relevant for creativity, and were even thought to hamper creative thinking. More recent studies, however, provide empirical evidence that EFs may be linked with creativity more than previously thought. This entry reviews this line of work, and suggests that the operational definition of creativity, as well as the stage of the creative process are important when considering the role of EFs in creativity.

EFs are control processes that regulate one's thoughts and behaviors. A number of EF models have been proposed, including the self-regulatory model (Barkley, 2012), problem-solving model (Zelazo et al., 1997), Lezak's conceptual model (Lezak, 1995), Miller and Cohen's model (Miller and Cohen, 2001), Miyake and Friedman's model (Miyake et al., 2000), and Banich's "cascade of control" model (Banich, 2009). Prefrontal lobe regions have been reported to be implicated in regulating EFs, including the dorso-lateral prefrontal cortex (DLPFC), anterior cingulate cortex (ACC), and orbitofrontal cortex, although other evidence suggests the involvement of additional brain regions as well.

Evidence for Low Executive Functions in Creativity

One line of work suggests that creativity benefits primarily from cognitive disinhibition. Cognitive disinhibition may allow more stimuli into people's conscious awareness, and allow them to notice information that other people may dismiss as irrelevant, enhancing the chances for a creative idea. Indeed, earlier studies reported that creativity is linked with diffused or "leaky" attention. For example, in a dichotic listening task more creative people are more likely to experience intrusion errors from the unattended ear. Similarly, more creative people are more likely to make use of "irrelevant" stimuli playing in the background while performing a memorization task. More creative people are also more likely to have low latent inhibition—i.e., the propensity to screen from conscious awareness previously irrelevant stimuli.

More recent work supports the potential role of lower EFs, such as “leaky” attention, in creativity. In one study, participants were asked to identify a target letter (S or H) within hierarchically constructed stimuli (i.e., large letters made up of small letters; Zabelina et al., 2016). Critically, 50% of the letters were congruent, where the large and the smaller letters were the same (e.g., large S made up of smaller ss), and 50% were incongruent, where the large and the small letters were different (e.g., large S made up of small hs). Thus, if someone’s attention is more “leaky,” they would respond quicker on the congruent trials, but slower on the incongruent trials. The congruency effect, i.e., how much faster people responded on the congruent, compared to the incongruent trials, was a measure of the congruency effect. Indeed, higher creativity was significantly correlated with a larger congruency effect, suggesting that more creative people may have “leaky” attention (Zabelina et al., 2016).

Neurophysiological studies provide confirming evidence for the link between creativity and cognitive disinhibition. Both earlier and some recent studies (for review, Benedek, 2018; Stevens and Zabelina, 2019) find that alpha-band activity—activity that is often linked with relaxation and disinhibition, is associated with creative states. However, other recent work questioned the role of alpha-band activity in creative thinking, proposing that alpha power reflects internally focused attention rather than disinhibition per se (Benedek et al., 2014).

Cognitive disinhibition has been discussed as the common link between the reported associations between creativity and some forms of dimensional psychopathology traits, namely psychoticism and hypomania (Zabelina et al., 2014), and the personality trait of openness to experience (Silvia et al., 2009), although the “mad -genius” controversy remains contentious.

Evidence for High Executive Functions in Creativity

Opposing evidence comes from studies that suggest that creative thinking relies largely on good executive functions, and may not be so different from intelligence. A recent study has shown that divergent thinking is linked with the ability to update concepts in working memory (Updating), while people who work in the artistic domains show better mental set shifting abilities, as well as successful regulation of their thoughts and behaviors (Zabelina et al., 2019). More creative people are also likely to inhibit more prepotent responses and show better working memory abilities. Finally, brain regions that are involved in cognitive control, such as inferior frontal gyrus (IFG) and inferior parietal cortex have repeatedly been shown to activate on tasks requiring creative thinking.

A Complex Interplay

Recent evidence points to a more complex interplay between controlled and uncontrolled processes in creative cognition. Such interplay is evident at the person, process, and the brain levels, and may also depend on the operational definition of creativity.

Individual Level

It is possible that at the individual level, both controlled and uncontrolled processes are involved, but are evident at different levels of cognition. Namely, at the bottom-up level, more creative people may be likely to experience cognitive disinhibition or “leaky” attention, as has been suggested by a number of investigations. At the top-down level, creative people may excel at controlled processes as well, as has been suggested by others. Indeed, creative acts, such as writing a novel or designing a complex computer code often require controlled processes like focused attention. Future work will need to investigate executive functions at the bottom-up versus top-down levels in creative individuals.

Process Level

The role of executive functions in creativity may also differ at the process level. Since the time of Wallas (1926), the creative activity has been discussed as a multi-stage process, where the primary stages include preparation, incubation, illumination, and verification. Thus, lower executive functions may benefit some stages of the creative process, such as incubation, while good executive functions may benefit other stages, such as preparation or verification. Indeed, during the preparation stage, persistence and focus may serve someone who is looking to learn what is already known in the field and what issues can be addressed further. Indeed, deep thinking has been shown to reduce shifting flexibility and increase task shielding. During incubation, however, it may be best to release cognitive control to let the ideas flow in.

Brain Level

Neuroimaging evidence provides strong support for a complex interplay between controlled and uncontrolled processes in creative thinking. This evidence comes from a number of recent functional magnetic resonance imaging (fMRI) studies examining dynamic brain network interactions, particularly between the default-mode (DM), the frontoparietal control (FPC), and the salience networks. The DM network is comprised of midline and parietal regions that activate during task-unrelated thinking, such as mind wandering, autobiographical retrieval and episodic future thinking. The FPC network is comprised of anterior parietal and

lateral prefrontal regions, and is thought to play a role in deliberate attentional control. Insula, the primary hub of the salience network, is involved in switching between the DM and the FPC networks.

Creativity has been repeatedly shown to be linked with dynamic interactions between the DM and the FPC networks both at the process level (during tasks requiring creative thinking, and during the certain stages of the creative process), and at the individual level (in people who are thought to be more creative). Specifically, on a divergent thinking task, on which people are asked to generate a number of creative uses for a common object, such as a brick, early stages of the creative process show co-activation of the DM and the salience networks, while later stages exhibit co-activation of the DM and the FPC networks (Beaty et al., 2014). In other studies, idea elaboration (Ellamil et al., 2012) and poetry evaluation (Liu et al., 2015) were associated with increased co-activation between the DM and the FPC networks as well. Christoff and colleagues proposed a dynamic framework model where creativity is thought to involve dynamic and rapid switching between the controlled and uncontrolled processes (Christoff et al., 2016). At the individual level, people who perform better on divergent thinking tasks similarly show coupling between DM and the FPC networks at rest (Beaty et al., 2014).

Operational Definition of Creativity

The degree to which executive functions play a role in creative thinking may depend on the operational definition of creativity. Currently divergent thinking tests are the most widely used assessments of creative cognition. Recently, other measures, such as semantic distance (the degree to which two terms are related), have been employed as a way to examine creative thinking. In line with the results on divergent thinking tests, increased semantic distance has been shown to be linked with the dynamic interaction between the DM and the FPC networks (Green et al., 2015). Other work has confirmed that both DM and the FPC networks are involved in creation of metaphors, and detection and appreciation of humor, both of which have been used to operationalize creativity.

Conclusion

Earlier discussions of the executive functions and creativity have primarily focused on the importance of uncontrolled processes in creativity. Later models discussed the involvement of good executive functions, such as focused attention and fluid intelligence in creative thinking. Mounting recent evidence, however, points to a more complex interaction between controlled and uncontrolled processes in creativity. Such evidence comes from work on individual differences in creativity, the examination of the various stages of the creative process, neuroimaging studies of the large-scale brain network interactions, and on the importance of considering operational definitions when examining the construct of creativity.

Glossary

Auditory Network This set of brain regions consists simply of primary auditory cortex (on the upper plane of the superior temporal gyrus) and neighboring, secondary auditory regions along the posterior and anterior superior temporal gyrus (This network is colored yellow in Fig. 1).

Default-Mode Network A set of brain regions (particularly medial prefrontal cortex and posterior cingulate cortex) that show greater activity during diffuse states of consciousness (such as daydreaming), internal direction of the attention, and spontaneous mentation (This network is colored red in Fig. 1).

Evaluative Phase This phase is an integral part of the creative process, which, however, must come after ideas have been generated and/or transformed in the above phases. Composers (and other creators) often seek to suspend evaluation until well after sufficient material has been generated, as evaluative processes can seem to suppress generative processes. Particularly in the case of artistic creativity (including musical creativity), this phase is associated with activity in the salience network.

Executive Network A set of brain regions (particularly dorsolateral prefrontal cortex and inferior parietal cortex) that show greater activity during tasks that require complex cognitive (top-down) control and active maintenance and/or manipulation of working memory contents (This network is colored green in Fig. 1).

Generative Phase This phase is predominantly passive and dreamlike, during which creative thoughts appear to generate themselves (bottom-up). The Generative phase has been predominantly associated with activity in the default-mode network, particularly (in the case of musical creativity) in cooperation with the motor planning network.

Motor Planning Network Integral to the planning of complex motor acts such as those characteristic of speech and tool use, this set of regions (particularly premotor cortex and the supplementary and pre-supplementary motor areas) is equally integral to musical capacities, both perceptual and productive, and particularly those that are most “creative.” (This network is colored blue in Fig. 1.)

Note-and-duration sequences While the term “musical creativity” can be interpreted extremely broadly, the restricted definition used in this article is the generation of novel patterns of notes and durations—i.e., patterns (or melodies/sequences) that are not already familiar to the composer/improviser.

Phases of the Compositional Process As creativity is not a single cognitive act but a complex set of interacting processes, it is valuable to subdivide the larger construct into phases, such as the generative, transformative, and evaluative phases.

Salience Network A set of brain regions (particularly the insula and anterior cingulate cortex) that show greater activity when the attention is captured (bottom-up) by stimuli reflexively deemed to be significant. The amygdala and other subcortical structures are often included in this network of regions (This network is colored purple in Fig. 1).

Sequence Music differs from the plastic arts (e.g., painting and drawing) in that musical works do not exist “all at once,” but necessarily unfold over time. For the brain to represent a musical melody (or other short passage), it therefore must build a mental representation for a string of events that connect to one another, at both the short-range (events immediately preceding and following) and the long range (e.g., noting a melody’s recurrence later in a work, and possibly the differences in the later iteration relative to the initial presentation). Across animal studies, such strings of complex motor and/or perceptual events are referred to as “sequences.”

Transformative Phase This phase is active and controlled, typically guided by internalized goals and the conscientious application of the recombinative “rules” of traditional composition and improvisation training. This phase has been predominantly associated with executive network activity, particularly (in the case of musical creativity) in cooperation with the motor planning network.

Introduction

Of all the creative arts, music is one of the most iconic, with images of Beethoven, Bach, and Mozart looming large—often quite literally—in the pantheon of western musical culture. Add to this the cults of personality that have arisen around equally influential musical creators such as Louis Armstrong, Miles Davis, Elvis Presley, the Beatles, Madonna, and Beyoncé, and the conclusion is inevitable: culture is massively influenced by the creative art form referred to as “music.”

Defining Musical Creativity: The Generation of Novel Note-and-Duration-Sequences

What, then, is “music,” and what specifically does it mean to be “creative” in music? The question is obviously a vast one and can only be addressed cursorily here. At the broadest scale, “music” could be defined as any intentional manipulation of sound patterns, typically for the appreciation of an audience. To be “creative” in music, therefore, could be defined as to manipulate sounds in ways that are novel, and thus function to influence the relationship between creator and audience. As such, creativity in music can be understood to encompass a large range of behaviors, from the obvious acts of composing and improvising to the more subtle but still “pattern-manipulative” acts of interpreting classical works, arranging and reharmonizing jazz standards, and even—as David Rosenboom has convincingly argued—simply listening to music actively and imaginatively. For simplicity’s sake, the present article restricts this broad focus by defining musical creativity as “the generation of novel note-and-duration sequences.” In this sense, the focus is predominantly upon the acts of composition and improvisation. However, it should be noted that this definition does not apply solely to professionals and students in these fields, but rather includes virtually anyone who invents a melody—even a bird or whale—as being “musically creative.”

Musical Creativity Versus Other Forms of Creativity

While creativity shares features across fields, there are aspects of musical creativity that are relatively unique to it.

1. *Speed.* The act of creating music, particularly in the case of improvisation, is often extremely rapid. Such “real-time composition” (as improvisation is often called) requires not only a precise command of fine-grain musculature (e.g., the fingers, mouth, and/or larynx), but also the capacity to execute those commands at sub-second levels temporal precision.
2. *Temporal extension.* Like film, dance, and storytelling, but unlike painting, sculpture, and architecture, music is a temporal art, requiring time to unfold. Thus for both the composer/improviser and the listener, the working memory apparatus plays a critical role in assembling a mental representation of the whole of the musical work—since the whole does not really “exist” at any single point in time except in the form of memory (ignoring “prosthetic” memory representations such as written scores and audio recordings).
3. *Symbolic structure.* Just as spoken words and sentences are constructed from a limited set of phonemes, so too are musical melodies constructed from a limited set of notes and durations. In this sense they are both “symbolic,” i.e., composed of “symbols” (or “elements”) which in themselves have no meaning. However, an important distinction between speech and music is that phonemes, when combined in specific ways, do produce recognizable “words” which can refer to events and objects outside of the language system itself, and thereby take on meaning. In contrast, recombinations of musical elements only rarely refer to anything outside of the realm of music. The fact that these different combinations of musical elements can still feel “meaningful” to a listener, therefore, is a peculiarity of the art of music that is worthy of paying special attention to.

Phases of the Music-Creative Process

Creativity in music, as in other fields, is not a single cognitive act but rather a set of processes. Based upon a survey of writings from composers from as far back as the classical era (as synthesized by writers such as Ian Bent), the compositional process can be subdivided into the following three phases.

1. *The Generative Phase.* Many composers (and improvisers) state that their best ideas come to them unbidden, particularly when they are in a dream-like or semi-conscious state (e.g., Brahms, Mozart, Reicha). This phase is therefore largely a passive one, although composers may actively seek to enter such states, and they often develop elaborate rituals for capturing with high fidelity (whether in written or audio format) the fruits of such dreamy labors. In the words of Brahms, for instance: “[Inspiration] cannot be [achieved] merely by will power working through the conscious mind ... I have to be in a semi-trance condition to get

such results." When inspired, however, "I immediately feel vibrations that thrill my whole being ... Straightaway the ideas flow in upon me ... and ... are clothed in the right forms, harmonies, and orchestration. Measure by measure, the finished product is revealed to me when I am in those rare, inspired moods ..." (Abell, 1955, p. 5).

2. *The Transformative Phase.* While composers tend to consider the generative phase to be a critical one, it is rare for them to suggest, as Brahms seems to do above, that the entirety of a musical work can come to them fully formed. Brahms in fact clarifies later in the interview that "of course, a composer must have mastered the technique of composition, form, theory, harmony, counterpoint, [and] instrumentation" for ideas to be "revealed" in such a way, and that "my compositions are not the fruits of inspiration alone, but also of severe, laborious and painstaking toil" (Abell, 1955, pp. 5–6, 59). For Brahms and many other composers, the generative phase is necessarily succeeded by an active process of consciously and conscientiously working with one's materials—manipulating them according to the rules of counterpoint, for instance—a process which is typically treated as the bulk of the "work" done by the composer.
3. *The Evaluative Phase.* Finally, while both the generative and transformative phases can be seen predominantly to increase one's store of material, clearly not all generated materials can be used—they must be evaluated. In music as in other fields, evaluative processes are often experienced as discordant or even competitive with generative processes, and thus relegating them to a distinct phase is not an infrequent recommendation.

Though presented as successive here, these behaviors may not occur linearly in real-world creative contexts, but rather may alternate rapidly according to task demands. Particularly for the case of improvisation, as compared with written composition, generative behaviors may be seen as more typical of live performance, whereas transformative behaviors may be more typical of how musicians prepare for performance—and thus may precede rather than succeed the former.

Musical Creativity from the Neuroscientific Perspective

Given the complexity of the set of behaviors falling under the construct of "musical creativity," it is not immediately obvious how this construct could be rigorously investigated from the neuroscientific perspective. Admittedly, that which is currently known about the neuroscience of musical creativity is only a tiny fraction of what one might ultimately wish to know to generate a proper "theory" of the creative musical brain. Nevertheless, the neuroscientific work that has been done on the subject, particularly over the last decade, has yielded insights that could not have been imagined through the use of humanistic (insight-based) techniques alone, and therefore offers a unique contribution to the understanding of musical creativity.

Historical Review

The pioneering study in the field was conducted in 2008 by Charles Limb and Allen Braun, who recruited six professional jazz pianists to improvise while having their brains "scanned" with functional magnetic resonance imaging (fMRI). Such a procedure tracks the flow of deoxygenated blood in the brain in real time, giving a sense of which brain regions have used more oxygen during a task, and hence which are likely to have been "active" during the task. The authors found that, when improvising, compared with playing a memorized melody, the musicians showed greater activity not only in auditory and motor-planning regions (as might be expected), but also in a set of regions implicated in internally-directed attention called the "default-mode network." Additionally, the authors reported reduced activity in "emotional" or "limbic" regions, and in a set of regions that is often found to act in opposition to default-mode regions, referred to as the "executive network." A subsequent investigation from Dr. Braun's laboratory (led by Siyuan Liu) reported comparable findings for improvised rap performance, as have a number of studies from other laboratories since that time. Such initial findings therefore seemed to support the notion that seasoned improvisers might go into a "defocused" cognitive mode when improvising, resembling the "dreamlike" or "semi-conscious" generative state described by composers such as Brahms and Mozart.

However, several other studies reported the almost precisely opposite finding—that default-mode activity reduces during improvisation (rather than increases), while executive mode activity increases. This "paradox," to quote the author, was elegantly resolved in a pair of studies by Ana Luísa Pinho and colleagues published in 2014 and 2015, which paid particular attention to the degree of improvisation-specific musical experience participants had (compared to classical music experience), as well as to the specifics of the improvisatory task assigned (contrasting a "pitch-set" task, which was assumed to be more cognitively demanding and restrictive, with an "emotional" task which was assumed to be less restrictive). Indeed, it was found that default-mode and executive network activity varied as a function of both experience and task: subjects with more improvisation-specific experience showed greater recruitment of the default-mode network and less executive activity than those with less experience; and the less restrictive "emotional" task similarly recruited more default-mode activity and less executive control than the more restrictive, cognitively demanding "pitch set" task. In other words, when tasks were "easier"—taking into account the participant's degree of improvisation-specific training, the restrictiveness of the task demands, and the degrees of freedom inherent in the set of elements available for recombination (e.g., number of keys)—default-mode activity tended to be higher and executive activity lower; when tasks are "harder," the opposite pattern was observed.

Figure 1 Regions and networks of the human brain implicated in musical creativity. *Bottom left*: lateral view of right hemisphere; *top right*: medial view of right hemisphere. Networks are color coded: yellow, auditory; red, default; green, executive; blue, motor; purple, salience. Numbers refer to Brodmann areas. Abbreviations: AC, auditory cortex; aIPL, anterior inferior parietal lobule; AMYG, amygdala; aSTG, anterior superior temporal gyrus; CMA, cingulate motor area; dACC, dorsal anterior cingulate cortex; dPMC, dorsal premotor cortex; HG, Heschl's gyrus; MC, primary motor cortex; OFC, orbitofrontal cortex; PCC, posterior cingulate cortex; pgACC, pregenual anterior cingulate gyrus; PHG, parahippocampal gyrus; pIPL, posterior inferior parietal lobule; PP, planum polare; PREC, precuneus; pre-SMA, pre-supplementary motor area; pSTG, posterior superior temporal gyrus; PT, planum temporale; SMA, supplementary motor area; TP, temporal pole; vPMC, ventral premotor cortex.

Brain Networks and Their Interactions

The brain is obviously massively complex in both its structure and function. Structurally the brain is not homogeneous, like the liver or the blood, but consists of a vast diversity of neuron types which form an overwhelming number of individual nuclei which process information in unique ways. This structural complexity at the regional level is compounded by the large-scale folding patterns of the neocortex. While each hemisphere of the neocortex is actually a single continuous “sheet” of (several layers of) neurons, this sheet folds in itself in order to fit within the skull, and as a result forms the four classical “lobes”—frontal, occipital, parietal, and temporal (see Fig. 1).

Traditionally, scientists have sought to understand brain function in coordination with this large-scale folding pattern (and the smaller scale patterns within each lobe, such as the division of the temporal lobe into three gyri, one located superiorly, one inferiorly, and one in between). Auditory regions, for instance, are located on the superior (upper) plane of the superior temporal gyrus (colored yellow in Fig. 1), while motor regions are located along the posterior edge of the frontal lobe (colored blue in Fig. 1).

While these observations undoubtedly hold true, it has become increasingly common for scientists to investigate how regions cooperate with one another—i.e., form networks—when engaged in certain tasks (or even when “at rest”—i.e., without an explicit task demand from the experimenter). This focus on network activity has proven particularly important for understanding complex mental behaviors such as “being musically creative.” While specific cortical regions can be identified for sound perception (such as those on the superior temporal plane), or sound production (such as the motor and premotor regions that control the voice and hands.), no single cortical region has been—or is ever likely to be—identified as “the” creative part of the musical brain.

Auditory-Motor Interactions

Consistent with this view, an examination of the findings of previous studies on the neuroscience of musical creativity reveals no single “auditory region” (on the superior temporal plane) that is consistently implicated in creative musical behavior. Similarly, very few studies implicate primary motor cortex in musical creativity. What this suggests is that being musically creative is neither simply auditory nor simply motoric, but rather something having to do with their interaction with one another.

This conclusion is supported by two types of evidence. First, while the Limb and Braun study described above analyzed the degree to which deoxygenated blood flow increased or decreased in individual brain regions, recent studies have additionally examined the “functional connectivity” observed between regions, i.e., whether any changes in blood flow in one region correlate with changes in other regions. Such functional connectivity analyses frequently report enhanced connectivity between auditory and motor regions during music-creative states—as well as altered degrees of connectivity with hub regions of the default-mode, executive, and salience networks.

Thus, connectivity seems to be altered between auditory and “motor” regions during music-creative states. However, the “motor” regions most consistently implicated in music-creativity findings, as mentioned above, typically do not include primary motor cortex—i.e., the portion of neocortex which, when stimulated, elicits movement directly. Rather it is the higher-level “motor planning” regions which are most frequently implicated in such studies. These regions are referred to as “motor” regions, but more accurately they are the critical means of interface whereby the remaining regions of the neocortex access the motor system. Typically these regions contain “mirror neurons,” which respond both during the perception and the production of a motor behavior. Such mirroring was first observed with the visual system but has been convincingly demonstrated for the auditory system as well. When trained musicians hear musical passages, for instance, activity in premotor cortex resembles that which would be required to play the passage; and reciprocally, when trained pianists depress keys on a silent keyboard, auditory regions (secondary rather than primary) show activity corresponding to the sounds that would actually be heard were the keyboard not silent. The “motor planning” regions consistently implicated in musical creativity studies, therefore, can fairly justifiably be reconceptualized as “auditory-motor integration” regions. A short summary of the roles played by these regions is offered here.

1. *Premotor cortex.* While primary motor cortex (at the posterior end of the frontal lobe) controls the finest details of motor coordination, premotor cortex (just anterior to it) coordinates higher-level complexes of motor commands (e.g., the movement of the whole arm to play a note, rather than just the individual fingers). Even further anterior to premotor cortex is a second strip of cortex sometimes referred to as “pre-premotor cortex,” which may coordinate even more abstract complexes of commands (e.g., coordinating the trunk movements necessary to promote the arm movements that allow the fingers to depress certain keys). Premotor cortex may be particularly important for coordinating body movement with the brain’s visual representation of the external world (e.g., situating one’s hands on the keyboard relative to middle C).
2. *Supplementary, pre-supplementary, and cingulate motor areas.* While lateral cortical regions (such as premotor cortex) tend to be guided by external demands (e.g., following a conductor), medial regions tend to be guided more by internal forces. Thus the supplementary, pre-supplementary, and cingulate motor areas show the greatest involvement when a movement is self-initiated and/or guided by emotional state. The former two regions (supplementary and pre-supplementary motor cortex) are also implicated in both the timing of movements and the grouping together of multiple individual events into “chunks” (the rough equivalent of motives in music or words in speech).
3. *Inferior frontal gyrus.* Just anterior to premotor cortex in the inferior part of the frontal lobe is a region which, in the left hemisphere, is called Broca’s area, but more generally can be referred to as the inferior frontal gyrus (this region is labeled in Fig. 1 according to Brodmann’s classification scheme as areas 44, 45, and 47). Broca’s area is critical in speech, particularly in concatenating “chunks of chunks,” i.e., concatenating words into phrases, phrases into sentences, and perhaps sentences into larger discourse groupings (such as paragraphs). In music, a parallel function of Broca’s area (in the right hemisphere) appears to be allowing improvisers to string short motives together into larger musical phrases, promoting a kind of “grammar” of recombination—which can be both predictable (following basic “rules”) and yet novel (producing never-before-heard combinations). This is an idea which is likely critical to understanding the brain basis of musical creativity and will be returned to below.
4. *Putamen.* All cortical regions, but especially frontal regions, project to an underlying nucleus called the striatum (part of the basal ganglia), which aids both in the acquisition of new motor patterns/sequences (during learning) and in the selection of previously acquired sequences (during performance). Of the striatum’s three subregions (caudate, putamen, and nucleus accumbens), the putamen region is the most consistently implicated in the acquisition and execution of motor patterns, particularly for beat-based metrical motor coordination and perception (as opposed to raw interval timing that is not metrically/hierarchically structured).
5. *Cerebellum.* While the putamen is particularly critical for tapping to the beat in metrical sequences—with beats occurring at rates of between about 1 and three taps per second—the cerebellum appears to be mostly involved at a finer-grained level of temporal coordination—on the order of milliseconds rather than seconds. The cerebellum is also likely involved in coordinating the inputs across senses (as they relate to auditory-guided motor performance), including not only motor and auditory senses but also vision and somatosensation. A main function of the cerebellum may be to receive “efference copies” of motor commands that are being sent, and to therefore predict the sensory consequences of such commands, sending “error messages” back to the neocortex only to the extent that the sensory expectancies differed from the actual sensory signal received.

Other Networks

While the auditory and motor-planning networks appear to form the foundation of basic music-cognitive functioning, on their own they are likely insufficient to account for creative music cognition. At least three additional networks appear to play key roles in differentiating what could be called “normal” music-cognitive behavior from “creative” behavior.

1. *The default-mode network.* As noted above, default-mode regions are the most frequently implicated in studies of creativity, including musical creativity. Consisting predominantly of medial (rather than lateral) cortical areas—such as medial prefrontal cortex, posterior cingulate cortex, precuneus, and temporal pole (colored red in Fig. 1)—these regions have privileged access to the body's current feeling state and show enhanced activity during diffuse modes of consciousness (including both daydreaming and normal nighttime dreaming). Default-mode activity tends to be greater in participants scoring higher on creativity tasks, and in individual participants engaging in more vs. less creative tasks. This is particularly the case for tasks centered upon idea-generation, i.e., the generative phase of the creative process.
2. *The executive network.* Historically, the executive network—consisting primarily of dorsolateral prefrontal cortex and posterior parietal cortex (colored green in Fig. 1)—was characterized as working in opposition to the default-mode network, with executive regions more activate for tasks requiring focused, external direction of the attention (in contrast to default-mode regions, which were more active during unfocused and/or internally directed attentional tasks). More recently, however, this simple oppositional perspective has been revised. In part through developing new, more sensitive analytical techniques, Roger Beaty and colleagues in particular have promoted a more nuanced understanding of the ways in which the executive and default-mode networks interact during creative tasks—demonstrating that these networks may in fact be more cooperative and interconnected with one another in creative individuals and/or during creative tasks, rather than less cooperative/interconnected. The executive network is also frequently found to be more connected with motor planning regions during improvisation, suggesting a degree of top-down control over performed patterns of musical notes, and thus potentially corresponding to the transformative phase of the creative process as described above.
3. *The salience network.* A third network, referred to as the salience network, can be conceptualized as a link between the cognitive systems of the brain/mind and its emotion systems. When a new or surprising event (an event deemed “salient”) is perceived, activity in the salience network often has the capacity to override ongoing activity in executive, default, and other networks, thus effectuating the “capture” of the attention by the novel stimulus. Importantly, while salient stimuli are typically portrayed as coming from outside (a ringing phone, an evocative odor), they may come from within as well, as in a self-generated thought or melody. In the generative phase, therefore, this network may be important in recognizing that an internally-generated idea has presented itself. However, because of this network's basis in brain regions that use information about the body's current feeling state to assign “value” to encountered objects and events, the salience network (consisting predominantly of the anterior insula, anterior cingulate cortex, and amygdala; colored purple in Fig. 1), while potentially playing a subsidiary role in the generative phase, is likely a key player in the evaluative phase—particularly for artistic (rather than scientific) forms of creativity.

Generating a Novel Melody: A Speculative Proposal

While the findings summarized above offer valuable insights into the higher-level workings of the creative musical mind, they nevertheless leave unaddressed some of the more basic questions one might wish to know about musical creativity, such as “how does a brain generate a new melody,” i.e., a novel “note-and-duration sequence”? While seemingly simple, this question is still deceptively complex to be addressed, and arguably has not been satisfactorily answered by the existing neuroscientific evidence. However, by subdividing this larger question into sub-questions that have more direct answers, it is possible to speculate as to what might be going on in a human brain, mechanistically speaking, when a novel melody is created.

The following sub-questions will be addressed in turn:

1. How does the brain represent a familiar melody?
2. How does the brain read from this internal representation to perform, i.e., “re-create,” the original melody (whether aloud or in the imagination)?
3. What might be different in a brain (or brain state) that would lead to the creation of a new melody rather than the re-creation of a familiar melody?

Representing a Familiar Melody

In a thought-provoking essay on the representation of melody in the human brain, titled *Is There a Tape Recorder in Your Head?*, neuroscientist Josef Rauschecker pointed out that auditory cortices demonstrate excellent sensitivity to the spectral aspects of sound, such as pitch and timbre. However they are less capable of representing, at least on their own, the temporal properties of a sound stream beyond the length of a few notes—the equivalent in speech of single words and possibly short phrases. Just as frontal regions are necessary in speech for stringing together words and phrases into complete sentences, so too in music it appears that frontal regions may be necessary for stringing individual notes and short motifs together into even the shortest and simplest of melodies. Melodic representations, in other words—even those that have only been perceived but never performed—are likely not purely “auditory,” nor have a locus solely in the temporal lobes, but rather are in essence auditory-motoric, with a representation distributed across both temporal and frontal cortex.

The frontal regions implicated in stringing together motives to create a melodic representation are, as might be expected, the motor planning regions introduced above: premotor cortex, the supplementary and pre-supplementary motor areas, and Broca's area (in both hemispheres), along with subcortical regions such as the putamen and possibly the cerebellum. It is worth recalling that the representation afforded by this collection of regions may be highly multifaceted and even multisensory: while auditory regions may specialize in representing a melody's sonic aspects, premotor cortex may specialize in representing the spatial aspects of the motor behaviors required to produce it, and the supplementary and pre-supplementary motor areas may specialize in representing its temporal properties (such as its alignment with a mental "grid" of hierarchical rhythmical proportions, i.e., its metrical interpretation).

The pre-supplementary area has also been implicated in stringing together individual items—such as basic motor behaviors, potentially equivalent to individual key presses on a musical instrument—into "chunks," as well as cooperating with Broca's area and the putamen to string together the "chunks of chunks" that could conceivably amount to the representation of entire melodies, and possibly even larger sections of works (e.g., verses and choruses in popular and folk songs). The representation of melody in the brain is therefore likely highly distributed (not localized to a single region) as well as dynamically "assembled" in real-time (rather than being represented statically as a whole at any one point in time, except possibly in the case of highly familiar and simple melodies, such as "Happy Birthday").

Imagining a Familiar Melody

Now that a rough account of the representation of melody in the brain has been established, the two remaining questions are: how is such a representation "read from" when this familiar melody is "performed" (whether aloud or only in the mind); and what might differ in the case of performing of a melody (again either aloud or mentally) that does not already exist as a memory trace in the brain, but is created anew as an unforged path through melodic space?

In answer to the first question, the case of imagining (rather than performing aloud) the sound of a familiar melody will be considered, since this is a behavior that, while not specific to musical composition, is critical to it. As might be expected based on the previous discussion, to "read from" or "activate" a memory representation for a melody, both motor-planning and auditory structures are critical. Notably, this typically excludes primary motor and auditory structures, and instead relies upon secondary and associative auditory and motor structures.

When such imagery is active—i.e., when singing through a melody in one's head is intended rather than accidental—it seems likely that executive regions would be implicated (a supposition supported by the fair but not extensive number of extant studies on the subject). An interesting comparison can be made with melodic imagery that is not active but passive, i.e., unintended—such as when one has "a tune stuck in one's head" (often called an "earworm"), or alternatively when a composer has a novel melody spontaneously come to her, either during the normal waking state, in a dream, or in some hybrid state in between. In such cases, it may be the default-mode network (rather than the executive network) that is more active in driving the motor-planning and/or auditory networks. The evidence on this point is meager, but findings by Nicolas Farrugia (on earworms), Sibylle Herholz (on active imagery), and Sukhbinder Kumar (on musical hallucinations) offer at least partial support for the model offered here.

Imagining a New (Unfamiliar) Melody

Finally, having established a prospective account of how a brain mentally "performs" a melody from a pre-existing representation of that melody, it may now be inquired as to what might be different in a brain that, rather than re-creating a familiar melody from a pre-existing representation, instead invents a new one. It may seem incredible that the brains of composers and improvisers can readily do this, but if the parallel case of speech is once again considered, it will be recognized that all normal speakers of a language "improvise" and "compose" novel utterances virtually all the time—much more readily, in fact, than they recite memorized utterances verbatim (such as citing Bible verses). While any newly improvised sentence in an everyday conversation is of course not "entirely new," but rather recombines familiar elements (words, phrases, idioms, etc.), the same is the case with music improvisation and composition. It should, in theory, be no more difficult to account for how novel musical utterances are constructed than to do the same for novel spoken utterances. Such a comparison could be a potentially fruitful avenue for future investigation.

A second point of comparison can also be offered which ties together many of the themes developed in this entry thus far: the comparison between the creative state and the dream state. As mentioned above, one of the most consistent statements of composers made about their creative processes is the foundational importance of a "dreamlike" generative state, in which "the best" ideas often come to them unbidden, and in the case of some composers (such as Mozart and Brahms) may even lead to the generation of an entire work, as long as this "semi-conscious," dreamlike state of creation is not interrupted. Such descriptions of this generative compositional state more than superficially resemble the dream state: it is not simply that the feeling of this cognitive state is "semi-conscious" or "dreamlike," but much more significantly that it is typified by the (seemingly) passive reception of mental contents—contents which some part of the composer/dreamer's brain must of course be generating, but which seem to come from nowhere (or from a supernatural being, such as a god or devil). Dreams can on occasion be static and/or boring, but they are often interesting, even bizarre—and emotionally potent as well. When composers state that their "best ideas" come from such dreamlike states—or in Brahms' words, "the themes that will endure in my compositions all come to me in this way" (Abell 1955, 6)—they seem to be saying not simply that ideas come easily in such states, but that the ideas generated in such states

are actually better than those generated during normal waking consciousness—or what might be called “transformative” consciousness, the cognitive state characterized by the transformative phase.

As stated previously, the generative phase is characterized most consistently by default-mode activity, while the transformative phase likely aligns mostly with executive network activity. It may be no coincidence, therefore, that the dream state is characterized by enhanced default-mode activity, and reduced executive-network activity. The neurochemistry of the dreaming brain is better understood than that of the creative (musical) brain, and therefore, it may also be productive to investigate whether and to what extent the neurochemical signatures of the dream state—high acetylcholine levels and low serotonin and norepinephrine levels—also typify and/or influence creative (musical) states.

However, it should be noted that to be creative is not simply to be asleep! Composers and other artists have developed elaborate rituals for maintaining partial consciousness during their dream-like, content-generative reveries, and in seemingly all cases a kind of hybrid state between being asleep and being awake is described. Semi-conscious states may be multiple and varied, as indicated, for instance, by comparing brain activity in different types of meditative state (as described in a recent review by Rozalyn Simon and Maria Engström). In some cases default activity is increased, while in others it is decreased; similar observations would likely be found for executive network activity, and possibly salience network activity as well. There may be any number of “semi-conscious” states that practitioners of improvisation, composition, mediation, lucid dreaming, dream yoga, and the like are able to access. Quite possibly these correlate in some way either with activity levels in the networks described here, in their within-network connectivity, and/or in connectivity across networks (whether facilitative or inhibitory, or a mixture of the two). Together with the cognitive modes that may be more consciously vigilant (such as the executively “controlled” transformative phase) or open to external influence (such as the evaluative mode, afforded by the salience network), this eclectic view of the large number of ways the mind appears to be used during creative musical behavior bodes well for neuroscience’s contribution to the developing understanding musical creativity in the mind and brain.

Glossary

Attention a cognitive process of selectively concentrating on a discrete aspect of information while ignoring other perceivable information

Cognitive resources amount of activation available for information storage and processing the underlying cortical neural system

Locus Coeruleus a nucleus in the pons of the brain stem involved with physiological responses to stress and panic

Phasic pupillary response rapid fluctuation in the size of pupil

Pupillary constriction narrowing of the pupil also known as miosis

Pupillary dilation widening of the pupil also known as mydriasis

Tonic pupillary response elevated baseline size of pupil

Working memory a system responsible for the active maintenance and online manipulation of information over short intervals

Introduction

The pupil is the opening located in the center of the iris that allows light to enter the eye and reach the retina. The fact that the size of the pupil changes in various conditions was well known to early researchers. But in the last 50 years or so psychologists have been interested in the fact that changes in pupil diameter can index cognitive functioning. In general, the pupil dilates when participants are in condition of increased attention or cognitive load or of emotional or cognitive arousal. **Pupillometry is the study of such changes in pupil diameter as a function of cognitive activity.** Pupillometry is tightly linked to Locus Coeruleus (LC) neuron activation, which conducts the noradrenergic system in the whole brain. The LC and norepinephric system (LC-NE) are known to be involved in different processes including stress variation, memory retrieval or selective attention, on top of general functions such as arousal and the sleep-wake cycle. This entry explores the history and evaluation of pupillometry and how it is widely used in psychology to understand underlying neural mechanisms of various cognitive functions. There is also a discussion regarding how these functions relate to creativity and how pupillometry can be used as a tool to measure critical aspects of creative performance.

Brief History of Pupillometry and Its Measures

The word pupil comes from the Latin “pupilla”, which means little doll. It refers to the small reflected images one can see when looking in the eyes of another person. The fact that pupil size changes in various conditions was well known to early philosophers

and surgeons. The earliest records comes from Roman Physician Galen (129–216 CE) who used plants to dilate pupils during cataract surgery. Courtesans in medieval Italy used a special substance to dilate their pupils so that they could appear more attractive.

Early methods to measure pupil size variation were not very accurate and mostly relied on subjective observations by researchers in clinical setups. These researchers used various tools such as compasses, reticles, cross hairs and other optical devices or even black circle templates to find the best match with the actual size of the pupil. Later, the development of cameras allowed researchers to work offline on the still images of the pupil. Improvements such as increased number of pictures per second through cinematographic methods further allowed timeline representations of pupil size variations and they were called “pupillograms” (Lippold et al., 1967). But the process was still very tedious and time consuming. Researchers had to develop every picture, project each frame on a screen and then measure the pupil size with a compass or a ruler. However, in last few decades, pupillometry methods have expanded with the arrival of latest eye-tracking devices. Modern eye trackers are very accurate and allow monocular or binocular online automatic recording.

Pupillometry in Early Psychology

Researchers in ophthalmology and optometry have been aware of pupil behavior for a long time. But the interest in pupillometry in psychological studies as a reliable measure of various cognitive processes is more recent. While task evoked pupil response from psychological effects were noticed in the 18th century, understanding of this phenomenon was lacking. Many early studies were personal observations of single patients in clinical studies. For example, Lowenstein (1920) studied the response of a catatonic schizophrenic patient for emotion, comfort, pleasure and displeasure. In another study change in pupil size was measured by adjusting cross hairs on a short focus telescope in an experimental lie detection situation (Berrien and Huntington, 1943).

Significant early work in psychology was generated by Hess and his associates’ at the University of Chicago. In one study, Hess and Polt (1960) showed that pupil size variation could be considered as an index of “arousal” and “implicit processing,” by measuring pupillary changes to pictorial stimuli in four men and two women. Pupillary responses were scored in terms of the percentage increase in pupil size in a test slide compared to preceding control slide. Women displayed relatively larger pupil dilation when they looked at pictures of babies, mothers with a baby or nude males than to other pictures of people. Heterosexual men’s pupils were found to be larger when they looked at pictures of naked women. In another study (Hess, 1965), pupillary response of food deprived participants was at least two times greater than non-deprived participants when they looked at pictures of food. Hess interpreted pupil dilation in these kinds of situations as an index of “interest”, “emotion” and “motivation”.

Since then other researchers have followed Hess in using pupil size to measure “emotion”, “interest” and “attractiveness”. For example, one of the studies (Fitzgerald, 1968), reported greater pupillary dilation in infants to pictures of human faces than to geometric shapes and patterns and to a picture of their mother’s faces as compared to that of a stranger. In parallel to these studies using pupil variation to assess “arousal” and “emotional responses”, researchers also noticed the relevance of pupillometry to index mental load. For example, in a study, participants showed greater pupil dilation during mental multiplication task (Hess and Polt, 1964). The more difficult the problems, the more pupil diameter increased. The impact of cognitive load in a mental arithmetic task was replicated in several studies. Similar effects were also found in other areas of research such as sustained attention processing, working memory, decision making and so on.

Pupillometry in Recent Psychology Research

In recent psychology research, pupillometry is a widely accepted as non-invasive, online and reliable measure of cognitive processing. It is used in various psychological research areas such as perception, language processing, memory, decision making and so on. In perception studies, pupil size has been shown to dilate and constrict in various imagined scenarios suggesting top down processing (Laeng and Sulutvedt, 2014). Pupillometry has also been used to study Subliminal Mere Exposure Effect (SMEE) where participants are familiarized to stimuli they cannot consciously perceive. Pupillometry has been a useful index of visual processing in the attentional blink task, which assesses whether participants notice the second of the two stimuli presented in rapid succession.

In language studies, pupil diameter proves a reliable index to various alterations to verbal language including alterations due to hearing loss (Kramer et al., 2013). Pupil dilation indexes the difficulty of word retrieval in bilingual participants, correlating with both word frequency and neighborhood density. Increased pupil diameter predicted the wandering of attention during reading tasks (Franklin et al., 2013). Similarly in decision making tasks, pupil dilation predicts decision threshold when a choice is made. Studies show that pupillary response indexes the decision making process as compared to the outcome. Memory research suggests that pupil change reflects retrieval as well encoding (Guillory et al., 2013; Kafkas and Montaldi, 2011). Pupil dilation is thought to index the strength of the memory and reflects stress levels during encoding tasks.

Physiology of Pupil

The pupil is the opening of the iris that permits light to enter the eye and reach the retina. In humans and many animals (but not all, e.g., domestic cats), the pupil is circular in shape. In low light the pupil tends to dilate whereas in bright light it tends to constrict. This phenomenon is called *pupillary light reflex*. Pupil diameter can vary from 2 mm to 8 mm and reacts to stimulation in about 200 ms. Usually in standard light conditions, pupil size is about 3 mm.

Variations in pupil size is caused by two smooth muscles in the iris: the “sphincter” (or constrictor) and “dilator” pupillae. The dilator muscle is under adrenergic control (sympathetic system) from the superior sympathetic ganglion. The sphincter pupillae is innervated by cholinergic fibers of the parasympathetic system leading to the stimulation of the dilator muscle and a parallel inhibitory parasympathetic mechanism. Pupillary response caused by cognitive load is tightly linked to “Locus Coeruleus” (LC) neuron activation. The LC is a subcortical structure and is the conductor of the noradrenergic system in the whole brain. The LC and noradrenergic system (LC-NE) are involved in different processes including stress variations, memory retrieval or selective attention. Single cell recording in monkeys have shown close connection and correspondence between the baseline firing rate of a LC neuron and pupil size. A recent work uniquely highlights the close relationship between the LC-NE system and the pupil diameter change relating pupil dilation to fMRI recordings of the LC (Alnæs et al., 2014).

Moreover, researchers have shown that the LC displays two main activation profiles: “tonic” and “phasic” modes. Gilzenrat et al. (2010) suggested that these two modes are two ends of a continuum. The “phasic” mode represents neurons firing rapidly to optimize performance during a specific task to focus attention on an exploration mode. This LC activation leads to rapid pupil dilation. The “tonic” phase, on the other hand, is more efficient in sustained processing. This mode is associated with an elevated baseline firing rate in the LC. It promotes disengagement from the task and diffuse exploration.

Pupillometry and Attentional Resources

As early as 1920 researchers argued that dilation of pupil can be observed with every increase in attention by intellectual processes of every kind. Since then changes in pupil size has been studied as a function of attentional resource allocation. Generally pupillometry is considered discriminately sensitive to different components of attention, based on the onset, acceleration or duration of dilation events. In other words, the delay, speed and length of a change in pupil diameter index various aspects of attention. A similar usefulness of pupil dilation to the study of attention has been observed before stimulus onset (implying anticipation) by manipulating asynchrony between the target and distractor stimuli in a flanker task, a procedure that measures response inhibition. Pupil dilation has also been studied to indicate mental load. For example, in one of the studies, gradual dilation was observed beginning with the presentation of the problem and reaching its peak immediately before the participants’ verbal report. The mean extent of the dilation was directly related to the degree of problem difficulty. Subsequent studies provided repeated evidence for the ability of pupil size to indicate mental activity to differentiate among different level of task difficulty.

Pupillometry and Cognitive Resource Allocation

All cognitive efforts, like physical efforts and sensory stimuli, cause pupil dilation (Beatty and Kahneman, 1966). Studies demonstrated that the pupillary response reflects an overall aggregate of mental resource allocation that is not limited to a specific part of the cognitive system. According to this view the pupil could thus be used to map overall functional level of the cognitive system to the amount of activity in the underlying neural system. Researchers have argued that pupil dilation amplitude is a useful measure of task evoked resource allocation. The more difficult a task, the more the pupil dilates.

Of course the amount of resources that are allocated to a task does not depend only on the cognitive demands of the task but also on the intensity with which an individual engages in it. This intensity of task engagement might also be reflected in pupil size variation. It has long been known that pupil dilation increases with the activation of sympathetic nervous system. As the sympathetic nervous system regulates arousal a higher pupil dilation may indicate that an individual is applying himself or herself with more vigor to the task at hand.

Working Memory

Working memory is the system responsible for holding information available for complex cognitive activities such as language, comprehension, planning and reasoning—all those activities that involve the representation and processing of how two or more elements are related to each other. It has been explicitly implied in conscious, controlled and deliberate information processing: “What we are aware of at a given time is represented in this working memory, through which conscious thinking flows in a sequential manner” (Evans, 2008, p. 259). Working memory is operationally defined as the number of items that can be recalled during a complex task that requires simultaneous maintenance of information in an active state and the manipulation of information for computational purpose. In simple words repeating a phone number can be done using plain short term memory and does not require working memory. But a task to retain a phone number and repeating it backward or backwards while skipping all the odd digits requires working memory.

Working memory is thought to be capacity limited. Theoretically, the capacity limit arises because only four or so items can be individuated and maintained through the continued allocation of attention. The ability to actively maintain items in working memory is critically dependent on the ability to allocate attention to items within working memory. If attention is distracted by internal or external information, the representations are not maintained, and performance suffers. Thus, individual differences in the capacity of working memory should partially come down to differences in the amount of attention that can be allocated to items, as well as in the ability to control attention and prevent fluctuations in attention.

Studies have used pupillary response as an online measure of attentional allocation and fluctuations in attention in order to examine both how attention is allocated to items in working memory and individual differences therein. Results of these studies

indicate that items in working memory are maintained via the continued allocation of attention and that individual differences in the capacity of working memory are partially due to differences in the amount of attention that can be allocated to maintain items in working memory (Unsworth and Robison, 2015). This phenomenon is reflected in the pupillary response.

Pupillometry in Intelligence Studies

Pupil dilation also allows for discriminating between individuals who differ in intelligence. For example, Ahern and Beatty (1979) analyzed task-evoked pupil dilation in two groups of university students differing in intelligence (as indicated by their scores on the Scholastic Aptitude Test [SAT]) while they were solving mental multiplication problems across three levels of difficulty. Individuals with higher SAT scores showed higher accuracy and smaller task evoked pupil dilation than individuals with lower SAT scores. As both groups did not differ in the magnitude of luminance induced pupil dilations, the differences in the task evoked pupillary response were assumed to reflect differences in central brain processes, indicating that more individuals invested fewer responses. In this regard, it must be noted that most of the intelligence studies have revolved around two hypotheses: resource allocation and efficiency. According to the resource allocation hypothesis individuals with higher intelligence show greater pupil dilation while performing intelligence tasks indicating allocation of greater cognitive resource allocation. But according to the efficiency hypothesis, individuals with higher intelligence show less pupil dilation indicating allocation of fewer cognitive resources.

However, in one of the recent intelligence and pupillometry study (Lee et al., 2015), individuals with higher intelligence showed greater pupil dilation indicating allocation of greater resource allocation for tough tasks than individuals with lesser intelligence and they showed lesser pupil dilation for relatively easy tasks. Based on this result, authors argued that individuals with higher intelligence have the ability to modulate their resource allocation strategies which gets reflected in their pupillary response.

Pupillometry, Intelligence and Creativity

Pupillometry studies on creativity per se is difficult to find. However, pupillometry has been used to connect the relationship between general intelligence, creativity, resource allocation and working memory. Correlational studies connecting creativity with general intelligence are available, but they are mostly related to creative fluency (the amount of generated insights and ideas) more than to originality and novelty commonly seen as the hallmark of creative performance. For example working memory and creative performance correlates with general intelligence and general intelligence may account for shared variance between working memory and creativity. In one of the recent studies the relationship between creativity and intelligence was explored from resource allocation perspective using pupillary response (Ojha et al., 2017). The results showed that individuals with higher intelligence scores showed greater pupil dilation during creative interpretation of metaphors than individuals with lesser intelligence. The authors argued that creative cognition requires allocation of various cognitive functions and may share underlying cognitive and neural mechanisms with intelligence.

Pupillometry, Working Memory and Creativity

Working memory is intimately associated with language, reflective consciousness, higher order control and the capacity to think hypothetically about future and counterfactual possibilities. Similarly, studies in cognitive neuroscience and psychology suggests that for creativity to emerge, sustained attention and executive control may be desirable if not necessary. Such executive control involves working memory leading to the straightforward hypothesis that working memory capacity positively relates to creativity.

To date, however, research into possible links between WMC and creative performance is sparse and pertains to creative fluency (the amount of generated insights and ideas) more than to originality and novelty commonly seen as the hallmark of creative performance. Moreover, the existing evidence is correlational and open to alternate explanation.

However, working memory fulfills two basic functions: to keep novel information in a heightened state of activity and to discriminate between task relevant and task irrelevant information. These two functions are critical in creative performance. First, creativity requires the overriding of habitual tendencies such as generating the most accessible but common ideas and relying on initial perspectives and insights. Second, creative performance requires the combination of concepts retrieval from long term memory into new ideas and problem solutions (ideas cannot be generated ex nihilo but build on existing knowledge). Therefore, it can be argued that working memory is related to creative cognition.

Moreover, Dual Pathways to Creativity Model (DPCM) can further show how working memory is related to enhanced creativity. DPCM proposes that creative outputs such as insights and original ideas are a function of cognitive flexibility, of cognitive persistence, or some combination of both processing strategies. The flexibility pathway captures the use of flat associative hierarchies and manifests itself in divergent thinking. Flexible processing leads to insights and original response because it facilitates accessibility of remote informational links and finding new connections among categories and concepts. Flexibility pathways are characterized by relatively low levels of cognitive control, more or less “automatic” spreading of activation and mind wandering and higher distractibility. Therefore, this pathway seems to be less dependent on working memory.

“The persistence pathway”, on the other hand, captures the notion that creative insights and originality need more or less deliberate, focused and structured exploration of a few cognitive categories or perspectives. To arrive at original ideas and insights, therefore, requires focused use of the available time. Accordingly persistence manifests itself in the generation of many ideas within a few

categories and in a strong association between time-on-task and cognitive performance indicating that time was used effectively. This pathway seems to be dependent on working memory as it is involved in tasks that require sustained and focused attention. Thus, flexibility and persistence alone or in combination lead to creative outputs and maybe engaged during creative performance.

Pupillary response is an online measure of various cognitive mechanisms, particularly of working memory, attentional allocation and fluctuation in attention. Thus examining how attention is allocated to items in working memory can provide insights into creative performance as well as and its underlying neural mechanism.

Measurement of Pupillary Response

Change in pupil diameter can be measured using a pupillometer or eye-tracker, which allows both monocular and binocular data collection. To analyze the data from the eye tracker various statistical tools such as SPSS, Matlab, etc. can be used. Prior to statistical analysis, data is cleaned and artifacts due to excessive blinking is removed and very small blinks are replaced by linear interpolation. Usually small blinks are defined as missing data for less than 3 seconds. In general data missing for more than 3 s are not used for analysis.

Moreover, pupil size can also be affected by external factors like luminance of stimulus and gaze angles. To correct them, various computational methods can be used. Usually the pupil data with a big difference (1 mm) between the left and right pupil size is removed. In general, the pupil size range is about 3 to 6 mm according to intensity level. Therefore, pupil data beyond the range of 2 to 8 mm is also removed (see Jang et al., 2014).

Then the change can be represented in terms of actual change in mm as compared to baseline data or in percentage. Note that the pupil size varies for individuals and therefore a representation in change in percentage gives a more accurate picture to generalize the results. Moreover, to compensate for individual characteristics, pupil size variation of a baseline task is used. Assuming the baseline data to be 100%, change in pupil size can be represented using the following formula:

$$\left(\frac{\text{experimental data}}{\text{baseline}} - 1 \right) \times 100$$

Methodological Limitations and Concerns

Pupil size can be influenced by variety of factors therefore it is important to consider the following concerns and limitations while designing pupillometry experiments. First, while pupil size can double due to luminance variations, changes due to cognitive load or arousal is rarely larger than 0.5 mm. Second, although pupillary responses are generally voluntary, people can learn to induce pupil dilation by mentally manipulating their thoughts (e.g. thinking about sexual images or doing mental arithmetic). However, people cannot inhibit pupil reaction to stimuli. Third, when fatigue develops, the average size of the pupil decreases and begins to fluctuate remarkably. Fourth, pupil size fluctuations are common under the effect of drugs and medicines. Fifth, a history of participants mental state such as depression and mood can also influence the pupil size variation. Therefore, designing a pupillometry task requires that researchers pay attention to those details that can cause pupil diameter fluctuations independently of the study purpose.

Spontaneous Eye Blink Rate

Spontaneous Eye Blink Rate (EBR) is closely related to pupil dilation. Several studies showed that eye blinks do not occur randomly. Spontaneous blinks indicate cognitive processing as well as mild cognitive impairment. Until recently, pupillary researcher treated eye blinks as missing data and used to fill in estimates of pupil diameter during eye blinks with an approximation. However, some independent studies indicated that eye blink bursts follow high cognitive load or information processing. This suggests that eye blinks reflect the release of resources used in stimulus related cognition. Blinks potentially reflect preparation and very short blinks are associated with errors on cognitive tasks, consistent with adequate preparation.

Pupil and blink data have been shown to explain independent variance in cognitive processing over 10 second intervals. However, pupillary and blink information do not correlate; they are completely independent. Pupil dilation often follows blinks on a cognitive task, which suggests that blinks reflect initial stimulus processing or preparation for engagement of cognitive resources. And as the complexity of task increases, pupil size increases but eye blink rate decreases.

Blinks also indicate concealment of crime related memories and deception. Some studies have suggested that eye blinks are controlled by the central nervous system and tend to inhibit it during sustained cognitive load and attention demand. Other studies indicated that blinking is avoided to maximize stimulus perception during high attention tasks and blink occurrence is reduced increasing information content and task demands.

Some studies found correlation between levels of dopamine and spontaneous eye blink rate. Eye Blink Rate can be used as a predictor of convergent and divergent thinking. Therefore, it can be argued that pupillometry in combination with blink rate analysis may provide better measurement and understanding of creative performance.

Conclusions

Pupillometry has evolved as a robust and reliable measure of cognitive processing in the last few decades within psychology and cognitive sciences. Many technological and methodological advancements have turned a once tedious, expensive and time consuming procedure into a relatively easy online process. Cheaper eye tracking devices have further allowed researchers with modest means to make use of this method to understand underlying mechanisms of various cognitive functions. It is proving to be a useful method to study special populations who are not able or willing to provide typical behavioral answers to certain research questions. Although, pupillometry is only beginning to be explored in creativity research and its potential has not been realized, in the future it surely promises to provide important insights into underlying cognitive mechanism of creative cognition and performance.

Background

The cognitive neuroscience of creativity is chiefly focused on identifying brain regions and networks that support creative cognition. Because creative cognition draws upon neurocognitive processes likely to be cornerstones of higher cognition broadly, these neuroscientific inquiries have attempted to parse particular kinds of creative thinking and the patterns of brain activity that support them. That is, rather than devise experiments to identify the ‘creativity’ part of the brain that is engaged for the sole purpose of creative cognition (which is unlikely to exist), psychologists and cognitive neuroscientists most commonly endeavor to present an association between activity within a specific brain region or network and a specific task that putatively estimates a specific form of creative thinking.

The bulk of this work has examined the neural bases of creativity through the use of functional magnetic resonance imaging (fMRI) or electroencephalography (EEG), relating brain structure, activation, and/or functional connectivity with specific operations of creative thinking. Recently, however, a growing number of researchers have employed noninvasive transcranial electrical stimulation (tES) to experimentally induce transient changes in neural activity of target brain regions. Whereas fMRI and EEG are used by investigators to correlate neural activity with a behavioral variable, tES allows for manipulation. Thus, tES can provide causal evidence for specific brain areas involved in distinct creative operations and may represent a viable method to augment creative thinking, at least in the short term. Insights obtained through the use of tES have bolstered our understanding of the neurocognitive processes involved in creative thinking.

Transcranial Electrical Stimulation

tES, the application of low-level electrical current to neuronal populations of interest, is a safe technique that allows experimenters to temporarily manipulate spontaneous (sometimes called ‘intrinsic’) neural activity of specific brain regions via electrodes carefully placed on the scalp. Electrical current is passed through the skull (as well as the skin and cerebral spinal fluid) to a target region of cortex hypothesized to be involved in a particular cognitive ability or behavior. In order to effectively and safely stimulate the region of interest, expert technicians computationally model this current by accounting for the different electrical conductivities of the different structural elements between the electrode(s) and cortex – including differences in grey and white matter. The technique does not cause neuronal firing, but rather, briefly alters the resting membrane potential of target brain regions, rendering them more or less likely to fire. Furthermore, these changes are short-lasting; tES does not lead to complete rewiring of neural connections or permanent alterations in resting membrane potentials. Thus, when exploring the effects of brain stimulation on cognition, behavioral assessments are typically performed within minutes of neural stimulation. Some have begun to investigate the ramifications of repeated stimulation, but there is presently little evidence of enduring neural changes.

There are several kinds of tES, but the most commonly used technique – at least with respect to creativity research – is transcranial direct current stimulation (tDCS). Traditionally, tDCS designs operate by passing current between two large, saline-soaked sponges: a cathode/return electrode and an anode/active electrode. The resting potential of neuronal populations under the anode is believed to increase, making these neurons more likely to depolarize (i.e., fire). The reverse is true for neurons under the cathode; stimulation lowers the resting potential, which decreases the rate of depolarization. In this way, tDCS has been used to either boost (via anodal stimulation) or reduce (cathodal stimulation) activity of select brain regions. If a cortical target is involved in a specific cognitive operation, then modulating activity at said region should influence the cognitive process in question. Such an approach

lends itself to both within-subject (compare performance before and after stimulation) and between-subject designs (performance of stimulated participants vs. unstimulated participants). To account for possible placebo effects, most stimulation studies will include a sham condition in which electrodes are placed on the scalp but, unbeknownst to the participant, there is no application of sustained electrical current.

The appeal of tDCS rests in the ability to intervene on spontaneous brain function. There are, however, a number of complicating factors that can make interpretability and/or implementation difficult. First, because the current must pass through the skull, scalp, and CSF before reaching even the most superficial part of cortex, it is challenging to stimulate deeper brain regions. For example, despite a theorized role in creative cognition, the posterior cingulate has eluded experimental manipulation via tDCS. This is further complicated by the fact that, even if it were possible to consistently reach such a region, current must first pass through more superior neuronal populations. Any behavioral effects could be attributed to changes in these areas. This is an issue even for 'easily' stimulated brain regions, as the current must travel between the cathode and anode, potentially influencing the resting potential of neurons located between the electrodes. It can also be difficult to estimate where current terminates (i.e., current may spread out from region of interest). These matters are all at least particularly mitigated by high definition tDCS (HD-tDCS), a newer kind of tDCS montage that consists of one central anode surrounded by four return electrodes, allowing for more focal stimulation.

Lastly, some interpretations of tDCS rest on a presumption of regional independence that has not been sufficiently empirically demonstrated. At present, there is still little known about how applying tDCS to one brain region may alter brain networks and create downstream changes to other regions. The sum of these complicating factors means that, even if tDCS to Region A results in some sort of meaningful change to Behavior A, it can be difficult to demonstrate that the change stemmed from alterations to Region A alone, and not from Region B – which may have been stimulated as current passed through the brain to Region A – or from changes in Regions C or D, which may be nodes of a brain network that also includes Region A.

Despite these issues, tES has been used to influence a range of cognitive abilities such as executive control processes, performance-related anxiety, and, as shall be explicated in the coming sections, creative thinking. Thus, tES can be viewed as a tool to elucidate neurocognitive mechanisms through the demonstration of dissociable changes in behavior (Elucidation of Neurocognitive Mechanisms of Creativity). If tES designs can reliably alter creative thinking (even over only brief periods of time), then it may also be used to induce lasting boosts in cognitive functioning (Potential for Creative Augmentation). The remainder of this chapter is devoted to these two uses.

Elucidation of Neurocognitive Mechanisms of Creativity

Creative cognition is most commonly said to rely on at least two primary operations: (1) divergent thinking, which refers to the expansive generation of novel ideas, and (2) convergent thinking, honing in on a single response from a number of possible alternatives. These two operations are typically measured with different creativity tasks that presumably depend more heavily on one or the other (although both divergent and convergent thinking are likely to be involved in any given creativity task). A standard – albeit imperfect – practice in the neuroscience of creativity is to specifically target one of these operations (through a certain task) and identify a brain region or network that correlates with behavior. Together, divergent and convergent thinking lead to what is commonly understood as creative cognition: cognition that results in ideas that are novel and useful. Given the complexity of creative cognition, it should come as no surprise that the effects of using tDCS to investigate the neural bases of creativity vary widely by task domain (i.e., divergent or convergent), polarity (anodal, cathodal), and stimulation site.

Divergent Thinking

Divergent thinking is theorized to depend on the availability of unfiltered, low-level perceptual information. In other words, individuals may display superior divergent thinking abilities when top-down control is reduced, thereby allowing for the consideration of a greater number of possible ideas and solutions that may be otherwise prematurely rejected. For instance, if one is asked to consider alternative uses of a brick, less inhibition may lead someone to generate more possible solutions. Scores on divergent thinking are typically derived based on the number of valid ideas an individual is able to produce, thus generating a larger number of potential solutions is likely to correspond to greater creativity. This line of thinking has received some support from tDCS experiments.

Across a number of studies, researchers have used cathodal stimulation to reduce the cortical excitability of left lateral prefrontal cortex (PFC), including left inferior frontal gyrus (IFG), a brain region with a well-established role in inhibitory control processes. Stimulation of left lateral PFC regions has led to improved performance on creativity tasks with an emphasis on divergent thinking. In one such study (Chrysikou et al., 2013), participants performed a variation of the traditional Alternative Uses Test (AUT) for which they were instructed to generate either common (non-creative) or uncommon (creative) uses for a set of everyday objects. Subjects who received cathodal tDCS over left PFC were faster to generate creative uses compared to sham. Notably, this was not observed for the common/non-creative condition – a dissociation that suggests that a hypofrontal state characterized by less top-down inhibition can boost performance on divergent thinking tasks that rely on unfiltered, bottom-up information (i.e., generating creative, uncommon uses), but not for tasks that depend on access to well-rehearsed knowledge (i.e., generating common uses). Other work has extended these findings. Cathodal stimulation of left IFG improved divergent thinking performance, while

anodal stimulation – which putatively increased inhibitory control – hampered creative production (Ivancovsky et al., 2018). Similarly, cathodal stimulation of left IFG increased fluency (i.e., number of ideas generated) and flexibility on an alternative uses task, but only when paired with anodal stimulation over right IFG (Mayseless and Shamay-Tsoory, 2015), rendering this result somewhat difficult to interpret.

Taken together, these studies provide some direct, experimental support for neurocognitive theories of creative cognition that emphasize the role of disinhibition during divergent creative thinking. Decreased spontaneous firing in brain regions involved in inhibitory control augmented divergent thinking. This suggests that individuals who display superior divergent thinking abilities may be better at disengaging cognitive control processes.

Convergent Idea Selection

If divergent thinking is about unrestricted expansion of thought, then convergent thinking can be viewed as the opposite; it is about directing thoughts towards a specific goal, evaluating the appropriateness of potential solutions, and ultimately choosing the optimal one based on the task at hand. Convergent thinking stems from one's ability to integrate concepts that may initially appear to be semantically unrelated. However, it cannot be overstated that seemingly all creativity tasks are likely to rely on both divergent and convergent thinking, making it difficult to truly assay these two processes and the neural mechanisms that give rise to them. That said, if a task depends more heavily on convergent thinking, then alterations to the resting potential of brain regions involved in idea selection and integration may improve task performance.

One brain region that fits this description is dorsolateral prefrontal cortex (DLPFC), which is involved in executive function, including promotion of task-relevant thoughts and suppression of inappropriate ones. Since convergent thinking is theorized to benefit from these mental operations, amplifying the spontaneous firing of DLPFC may lead to improved performance on convergent tasks. The Remote Associates Test (RAT) is the most frequently used measure of creative convergent thinking. The RAT approximates convergent thinking by providing participants with three seemingly unrelated words (e.g., 'Fish, Mine, Rush') and requiring them to identify a fourth word that forms a compound association with all three ('Gold'). There is a clear emphasis on appropriateness and selectivity – several possible solutions may connect two words, but only one links together all three. Consistent with this explanation, anodal – but not cathodal – tDCS of right DLPFC has been shown to improve RAT scores (Cerruti and Schlaug, 2008). Increasing the excitability of a region with a previously-established role in directing task-appropriate thoughts improved convergent thinking, whereas decreasing regional excitability did not. Furthermore, the same stimulation setup (i.e., anodal tDCS of right DLPFC) did not produce enhancements on a primarily divergent task. This separation indicates that, in accordance with prevailing theories of creative cognition, divergent and convergent thinking may be conceptualized as (at least partially) different forms of cognition with (at least partially) distinct neural bases.

The Thinking Cap Effect

Humans are able to deliberately think more creatively when provided with explicit instructions to do so. This so-called thinking cap effect demonstrates that creativity – in addition to being a trait that varies among individuals – can also be viewed as a state that is subject to change over time based on task context and goals. In looking at the tDCS literature as a whole, the overall body of work indicates that cognitive improvements are largest when paired with behavioral interventions (e.g., cuing or priming) that are likely to engage the same neuronal populations targeted by the electrical stimulation. This suggests that the effects of tDCS may be greatest when applied alongside a cue to 'think creatively'.

Another part of the brain likely to be involved in creative thinking – especially as it pertains to intentional increases in state creativity – is frontopolar cortex. Although the precise role of frontopolar cortex is not fully understood, it appears to be engaged for the purposes of combining pieces of information and integrating abstract representations. As previously noted, one of the great benefits of tES rests in its ability to extend prior correlational imaging work. This has been done particularly well with respect to the thinking cap effect.

After identifying left frontopolar cortex as a brain region associated with creative state enhancement during a verbal relational thinking task (i.e., more activity in this brain region was associated with a larger cue effect; Green et al., 2015), a follow up study (Green et al., 2017) was performed in which participants received anodal HD-tDCS to the same brain region while they completed similar relational thinking tasks. For one task (the matrix task; Weinberger et al., 2016), participants were explicitly cued to think creatively while they selected word pairs from a large matrix to form valid and creative analogies. In the second task (verb generation; Prabhakaran et al., 2014) participants were provided with noun prompts onscreen and asked to generate related verbs. They were cued to think creatively on half of the trials. Compared to those receiving sham, participants with anodal stimulation to left frontopolar cortex displayed significantly improved creative performance on the matrix task (which was always accompanied by a cue). On the verb generation task, there was a tDCS × Cue interaction for which maximal creative performance was observed when participants with anodal stimulation received a cue to think creatively. Together, this study highlighted the role of a specific brain region (in this case, left frontopolar cortex) in a specific creative process (thinking cap effect for relational thinking) by directly intervening on spontaneous brain activity.

It should also be noted that, by providing explicit instructions to think creatively, selectivity demands were effectively increased, further emphasizing the role of convergent thinking. For example, on the verb generation task, rather than name the first verb that came to mind, the cued participants had to search for more semantically distant connections and – from a now-larger collection of

potential solutions – pick the most appropriate option. This kind of reasoning is a defining characteristic of convergent thinking. Since frontopolar cortex appears to be involved in combining and integrating information, it would follow that activity in this brain region may increase when cued to think creativity because of a greater need to combine and integrate information. Additional work supports the interpretation of cue = greater selectivity. Anodal stimulation of DLPFC augmented performance on a convergent task but had no effect on divergent thinking (Zmigrod et al., 2015). However, when the same stimulation design was paired with explicit instructions to visualize using an object in an usual way (thereby increasing the number of possible ideas and the need for convergence/selectivity), tES did enhance divergent thinking (Colombo et al., 2015).

Potential for Creative Augmentation

The prior section provided an overview of some of the ways in which tES has been employed to provide causal evidence in favor of a specific brain region's involvement in a specific form of creative cognition. By applying electrical current to task-relevant brain regions, experimenters have been able to manipulate one's capacity to think creatively, but even the most promising findings in this area have come far short of demonstrating that tES is a viable way to induce long-lasting behavioral effects. However, transient improvements in creative thinking introduce the possibility of more enduring benefits, and open the door for a nuanced discussion regarding how/when such techniques may be utilized to boost creative thinking.

Treatment of Enhancement?

Should the use of brain stimulation to augment creative thinking be considered a treatment (i.e., something deemed therapeutically necessary for a healthy and/or normal life) or an enhancement (a non-medical improvement for career advancement and/or life-style changes)? The answer to this question could result in very different regulations pertaining to the use of tES for creative cognition. Broadly speaking, the use of brain stimulation to increase a specific form of cognition is commonly viewed as an enhancement, and this seems appropriate if one conceptualizes creative thinking as something involved in artistry or technical innovation. For example, an accountant who desires to be better at musical improvisation would have a difficult time claiming that becoming a better musician is medically necessary.

But what if the same accountant argues that their creative abilities are so poor that they have become clinically depressed? While one option would be to treat the depression itself, would it not also be appropriate to fix the cause of the depression (i.e., a lack of creativity)? In this instance, if tES were found to ameliorate mental health by restoring or improving some degree of creative thinking – even if it were just one part of a collection of clinical interventions – then it seems as though the treatment label may still be appropriate. Furthermore, generative and flexible thinking – cornerstones of creative cognition – are likely to have widespread utility. While it would be inaccurate to describe aphasia as a disorder of creativity, one could argue that aphasics who struggle to verbally express themselves may become anchored on certain words, and their inability to articulate a thought could be described as an inflexibility. Hypothetically, using tES to improve generative abilities – much in the same way that it may be used to increase the number of words a participant can generate during the AUT – could relieve some aphasic symptoms (again, along with other treatments). This illustration is speculative, but serves to demonstrate the challenges in deciding how best to classify efforts to use tES to foster creativity.

Relatedly, there is also the question of access. If the use of tES is classified as a treatment, then individuals could ostensibly have the cost of purchasing and maintaining a device at least partially covered by health insurance. This, in turn, would create an avenue by which a large percentage of the population may be able to obtain tES equipment to augment creativity. Alternatively, if deemed as an enhancement, medical coverage seems unlikely to be obtained. As a consequence, the theoretical benefits of recurrent use of tES would be offered to only the members of society with the financial means to purchase and use the devices. Such income-related differences in access would hardly be something new (e.g., private education, higher quality produce), but represent just one possible result of tES classification.

Contexts of Use

Deciding whether to classify tES-based augmentation of creativity as a treatment or enhancement may be a worthwhile exercise, but using brain stimulation to induce lasting changes is not presently feasible. A more pressing matter concerns contexts of use. tES devices are, at the time of writing, easily obtainable as direct-to-consumer products marketed for a variety of uses, such as improving mood and attention. These devices are designed to be safe, but unsupervised home users who wish to improve their creative thinking may not heed the provided instructions, increasing the possibility for misuse. Complicating matters further, a burgeoning do-it-yourself community has developed methods to modify commercially available products or simply make their own devices from scratch for the purposes of improving a number of cognitive abilities. Home-made devices are not bound to any safety standards, furthering increasing the potential for risk to the user. These matters are particularly concerning if individuals apply electrical stimulation to children, as little is presently known regarding how electrical stimulation impacts the developing brain. Creative thinking is a prized ability in modern society, and parents and/or teachers may wish to fortify it to bring about long-term professional success.

In looking at the collection of empirical studies described earlier, it is apparent that short-term facilitation of certain kinds of creative thinking is possible. Critically, however, because creativity is a construct that pulls from several different cognitive processes, there is a complex interaction between current (anodal, cathodal), stimulation site, instructions, and task. All research was carefully guided by prior neuroimaging and behavioral investigations that identified specific neural mechanisms that support distinct creative processes. Researchers are not merely zapping the creativity part of the brain. For this reason, it seems unlikely (although not impossible) that home-users would be able to target specific brain regions to induce changes to corresponding forms of creative thought. Furthermore, as noted at the beginning of this chapter, optimal tES electrode placement and current is determined through sophisticated modeling conducted by expert technicians. Direct-to-consumer devices, as well as those made and/or modified by home users, are typically more constrained than tES hardware used in the laboratory, meaning that, even if the correct brain region is targeted, limitations on delivery parameters may prevent users from obtaining the effects that have been reported in the literature. Outcomes achieved in the laboratory environment may not be predictive of effects in the home or school settings.

In reality, however, it is likely that use in the home and school setting will occur regardless of these hurdles, making it vital to evaluate if and how tES should be used in such contexts. The outright banning of certain kinds of equipment and use would be difficult to enforce, and may only drive this growing community of users further underground and away from potential regulation. Accordingly, many have argued that the inevitability of use outside of the laboratory setting obligates researchers and policy-makers to work together to more thoroughly evaluate in-home use and directly engage with the do-it-yourself community and commercial manufacturers.

Conclusions

The use of tES affords researchers the opportunity to experimentally manipulate, rather than passively observe, the relationship between neuronal activity and creative cognition. One prominent theory of creative cognition posits that reducing inhibition allows for a greater consideration of possible ideas, which in turn increases the capacity for divergent thinking. Convergent thinking, on the other hand, is believed to stem from executive function and the promotion of task-relevant thoughts. Both of these neurocognitive explanations have received some support from tES experiments. Reducing the excitability of brain regions implicated in inhibitory control induced improvements on primarily divergent tasks while increasing the excitability of frontal brain regions that contribute to goal-directed thought yielded better convergent thinking scores. When paired with an explicit cue to think creatively during relational thinking tasks, anodal stimulation to brain regions involved in information integration (i.e., frontopolar cortex) produced significant gains in creative performance. Similarly, anodal stimulation to DLPFC improved thinking on a primarily divergent thinking task when accompanied by a cue that increased selectivity demands.

At present, the primary value of tES rests in how it can be used to better elucidate the neurocognitive bases of creative cognition; the reported boosts in creativity are short-lasting. However, projecting into the future, there is little doubt that such augmentation may further infiltrate the public interest, leading to in-home use of tES for the purpose of generating lasting improvements in creativity. This introduces a number of significant neuroethical issues related to how such interventions should be allocated and regulated. Prior work has recommended a multistep process that can evaluate the utility of using tES to influence cognition while simultaneously taking efforts to mitigate risks by determining when, why, and in whom the technology should be used. As research continues to explicate the neural substrates of creative cognition, these issues will become increasingly pertinent.

Glossary

Attractor A region in the space describing the conditions (states) of a system, toward which the system will tend to go and tend to stay. *Strange attractors* characterize chaotic behavior and consist of confined trajectories that both converge and diverge, the system never in the same state and moving the same direction twice.

[☆] *Change History*: June 2019. David Schuldberg & Shan Guisinger updated the text throughout the article.

This article is an update of D. Schuldberg, *Chaos Theory and Creativity*, Editor(s): Mark A. Runco, Steven R. Pritzker, *Encyclopedia of Creativity* (Second Edition), Academic Press, 2011, Pages 183–191.

Bifurcation A system's qualitative transformation, accessing new states, changing its dynamics, or attractor. [Stephen J Guastello and Liebovitch \(2009, p. 1\)](#) provide an example of change from one type of system into another, from one with periodic motion to chaos. *Catastrophe* is a similar term, generally referring to discontinuous change in a system (Guastello, 1995).

Chaos A class of dynamic behavior in deterministic systems characterized by sensitive dependence on initial conditions, diverging but constrained trajectories that imply unpredictability, and complex organization or structure. *Complexity* is sometimes a synonym.

Complex Adaptive System (CAS) Systems whose elements, or *agents*, learn from interactions with one other ([Holland, 2014](#)).

Dissipative systems Systems, such as living systems and forming snowflakes, that use up energy. Also referred to as systems *far from equilibrium* or at the 'edge of chaos.'

Emergence The perhaps sudden appearance of a new regime of system behavior or a new system, such as from a periodic to a chaotic system. Includes the *emergence* of new forms, structures, patterns, or organizations. *Fractals*, or the formations of convection currents as water heats up, are examples.

Fractal A pattern with similar structure at different magnifications, 'self-similarity' at different scales; strange and other complex attractors generally have discernable fractal structures.

Nonlinearity A relationship between two variables or a causal relationship between components of a system that is *not* strictly proportional and thus cannot be represented as a straight line graph on ordinary graph paper.

State space A space containing representations of the possible conditions or locations of a system. A location in '*phase space*,' sometimes synonymous, describes not only the current condition ('state') of the system but also its velocity, and where it is heading next.

Stochastic Random, operating according to probabilities, as opposed to processes or systems that are *deterministic*. NLDS are *deterministic* and not *stochastic*.

Systems theory Theory describing the behavior of composite entities composed of changing, interacting, and connected parts or units whose functioning emerges from the mutual influences of the parts. Characterized by modularity, interconnectedness, holism, emergence, the whole being greater than the sum of parts.

Introduction

Nonlinear dynamical systems (NLDS) theory, popularly known as chaos theory, is an exciting area of mathematics with increasingly productive application in the physical, biological, and social sciences. Initially attractive because of their great metaphorical appeal, NLDS also add rigor, realism, and explanatory precision. This article describes how they help illuminate creativity, a seemingly magical phenomenon eluding easy explanation since ancient times. Such difficulty in itself may indicate it is a good candidate for NLDS explanations.

Chaotic or near-chaotic systems can demonstrate amazing flexibility and adaptability. Despite connotations of 'chaos,' they can show order, complexity, and self-organization. Relatively simple, mechanistic, non-random, completely deterministic systems – called here *Somewhat Complicated Systems* (SCS; [Schuldburg, 2002](#)) – are capable of both regularity and surprising change. The theory is finding specific application to human processes including consciousness, cognition, perception, motor behavior, affect, learning, development, attitude formation, social interaction, personality, and psychopathology. Applications are developing rapidly as new phenomena are explored with new models and related data analyses, applicable at both low-level or micro (e.g., neurochemical) and larger macro (e.g., societal), levels. This entry applies NLDS to theories and data about creativity.

Dynamical Systems: Linear and Nonlinear

NLDS theory describes the behavior of systems that change with time; this is what 'dynamic' means, classically referring to actions of forces producing motion. Secondly, it applies to systems where at least one relationship among the components is nonlinear.

Linear Dynamical Systems

In contrast, much work in mathematics and science historically has focused on linear systems, where change in one part results in proportional change in another; in these, the relationship between the magnitude of a variable and its effect on a second variable can be represented graphically by a straight line on ordinary graph paper.

Fig. 1 depicts a simple linear dynamical system consisting of a block resting on a frictionless surface. It is attached to a solid wall by a 'linear' spring whose restoring force is proportional to how far it is pulled or pushed (x).

$$F = k_1x$$

A graph of this equation – relating the spring's force and how far the block is pulled – is a straight line (**Fig. 2**, dotted line).

Figure 1 A linear dynamical system.

Figure 2 Linear and nonlinear springs ($k_1 = 16$; $k_2 = 0.2$).

If the block is drawn and released, it oscillates back and forth in a smooth, identically repeating pattern, easily modeled as a simple function of time. Linear systems have many desirable properties. Effects can be computed or disassembled as weighted sums of parts; they are often amenable to exact (analytic) mathematical solutions that precisely describe and predict their behavior. Research in psychology has mainly emphasized linear models. The product-moment correlation coefficient tests fit to a straight-line relationship between variables.

A Nonlinear Dynamical System

In contrast, NLDS theory studies situations where the relationship between one variable and another is represented by something other than a straight line. Nonlinearity is the rule in nature, with linearity a special case and often-useful simplification.

Discontinuous or all or none responses, such as the threshold firing of a neuron, are nonlinear ones. Another example is the restoring force of a nonlinear or 'hard' spring:

Figure 3 A nonlinear dynamical system.

$$F = k_2 x^3 \quad (x^3 \text{ is the nonlinear term})$$

The graph of force and distance pulled (x) for this spring is definitely *not* a straight line (solid curve).

Fig. 3 shows a small nonlinear mechanism constructed of two systems from **Fig. 1**, coupled in the middle with a nonlinear spring. With certain settings (springiness of the springs, masses of the blocks) it exhibits chaotic behavior.

Nonlinear Dynamical Systems in Life and Social Sciences

What specifically makes a system a nonlinear one? Discontinuous responses, ones that level off or drop, time delay, double-edged characteristics, and interactions among variables – all these introduce nonlinearity. NLDS can provide not-very-complicated causal models compatible with our experiences and observations of complex, patterned, often unpredictable behavior in ourselves and other living things. Despite being completely deterministic, their behavior can seem disorderly, noisy, random, alive! They also show surprising order and organization. Weather seems to change randomly but actually runs by the deterministic laws of Newton. The formation of snowflakes – nonidentical, but similarly formed – follows strict symmetry and results in uniquely beautiful objects.

NLDS' behavioral complexity promises ecologically valid explanations of real-world processes. But, they can be hard to work with and difficult, although not always impossible, to solve mathematically. This is one reason many avoided them before our widespread access to very powerful computing tools. You do not need to be able to solve their equations to use NLDS in research; broadly available software allows modeling, visualization, and simulation of diverse interesting systems.

Interesting Behaviors and Characteristics of NLDS

Some of these characteristics are associated with NLDS in general; others, such as strange attractors, apply specifically to chaos and complexity.

Temporal Change (Dynamics)

By definition, dynamical systems (both linear and nonlinear) change. Human activity is change with time. Psychological and social systems are in flux. Despite longitudinal approaches, much research still utilizes cross-sectional (single time) data or emphasizes the short-term, such as from pre- to post-test.

Unpredictability: Sensitive Dependence on Conditions

For some systems behavior is easily forecasted, for example, the linear device in **Fig. 1**. Others don't have mathematical solutions. There are two issues here. One concerns reducing systems' motion to an equation, solving a system 'analytically.' This can be difficult for many nonlinear systems, chaotic or not. The second: NLDS can enter regimes of chaos. A defining characteristic of chaos is *sensitive dependence on initial conditions*, where small differences in beginnings lead to large differences later; this also holds for outside perturbations. Small unknowns at the start of a story, environmental input, subtle influences along the way, all might have big consequences; this is the main sense of the famous 'Butterfly effect.' Visualizing the changing *phases* (see below) of a system as describing a track over time, very close paths can diverge radically later on. Unless its position and motion are known exactly, one cannot say accurately where the system will be later. This limits our ability to predict the future or ensure what happens next, as with the weather more than two weeks out and the course of a life.

While this may seem superficially similar to *Quantum Uncertainty*, the Heisenberg Uncertainty Principle operates only at extremely small, subatomic scales. The unpredictability of our larger-scale, chaotic, creative bio-psycho-social systems does not come from minute Heisenberg or quantum effects. Rather, macro-level unpredictability is fully compatible with completely Newtonian (non-quantum, non-relativity, pre-Einsteinian) physics and mechanics. This distinguishes deterministic chaos from quantum uncertainty, and from the true randomness of genuinely stochastic, chance, non-deterministic processes.

Social scientists generally use deterministic models, yet remain puzzled by failures at prediction and control in behavior, policy, and intervention; lives can thwart even our own attempts to steer them. But, difficulties in forecasting and control are simply properties of real life in a nonlinear (but still non-random) world.

Some Regularity Without Identical Repetition

Variability in systems has been attributed to noise, measurement error, and the effects of extraneous variables. However, it is often instructive to ask whether observed fluctuation actually represents data. NLDS analyses can expose patterning and processes

underlying seemingly meaningless change when we attend more closely to apparently random fluctuation, unexpected blips and swings, near-regularity, complex repetition, contained cycles, stable oscillation, and dynamic 'equilibria.'

This extends interest to bifurcations, both positive as well as negative feedback loops, unstable equilibria, and dynamic 'stationary states.' Much human behavior appears only approximately regular and sometimes 'out of the blue;' homeostatic regulation is chaotic, allowing reorganization, adaptation, development, and resistance to inner and outer perturbation or entrainment.

Bifurcation and Catastrophic Change

Another characteristic of dynamical systems is the possibility of bifurcation, qualitative system transformation with access to new states, splits into different kinds of dynamics, or changes in an attractor (Guastello and Liebovitch, 2009, p. 14). A system may shift from periodic to chaotic with different parameter values. The appearance of new systems is one meaning of 'emergence.' Some of these shifts are called catastrophes or represent 'tipping.' Seemingly discontinuous and radical psychological changes include psychotherapeutic Aha! Experiences, or an alcoholic's 'falling off the wagon' or committing to sobriety. These are modeled by catastrophe theory, a part of NLDS theory.

Chaotic and Complex Behavior

Not all NLDS are in chaos; however, the possibility of chaos is a very compelling feature.

A system's *phase* refers both to the location of its elements at a given time, and to where it is heading next. An *attractor* defines a region in *phase space* where a system tends to go, linger, or stay. A *fixed-point attractor* represents a unique place a system approaches and remains. If friction is added to the system in Fig. 1, the block will slow and eventually stop; this attractor is a point in phase space. A clock pendulum describes a *periodic* or *limit cycle* attractor; keep the mechanism wound and the pendulum returns to the same regular swing even if bumped.

In contrast, the never-repeating paths of chaotic systems are characterized by 'strange' attractors (a term that still delights after nearly 50 years). Viewed in phase space, chaotic systems never precisely go through the same place with the same velocity (speed and direction) twice. These regions in phase space contain ever-different, never-crossing paths. Close-together but not identical points can diverge, with vastly different outcomes later. Strange attractors are ever-changing, with originality and constant innovation; they include both order and disorder, convergence and divergence.

Scaling, Symmetry, Self-similarity, and Fractals

Strange attractors have interesting structures, including fractal patterns, self-similar at different scales. Similarity over different instances, temporal scales, and locations is related to Wittgenstein's 'family resemblance concepts,' and to the notion of creative 'style' across works, materials, and career. Self-similarity but not self-identicalness also provides an account of people's consistency in the face of the flamboyant self-contradiction central to the human soul. Obvious at different scales, consistency does not mean people will do the same thing, even in similar situations. Approaching personality styles as strange attractors with fractal structure reconciles personal identity and behavioral variability. Similarities across scale are common in clinical psychology in 'miniature' enactments of life issues in therapy, recapitulations of old interpersonal patterns (Marks-Tarlow (2008)). This 'parallel process' represents interpersonal self-similarity, like re-capitulation and re-figuring across levels and scales in archetypal processes in art.

Because of their scale properties, fractal phenomena also demonstrate interesting 'inverse power law' or 'long-tailed' distributions rather than familiar bell-shaped curves. Also visible in temporal phenomena like a faucet dripping, fractals suggest combined linear and cyclic versions of time and space. Seemingly predictable epochs are regions around attractors, entered, orbited, and left; at these times, life appears repetitive, with nearly symmetrical beginnings and endings, rising and falling narrative-like episodes. Then the story changes, reversal, new attractors.

Dissipative Systems and the Edge of Chaos

The edge of chaos occurs in high energy (far from equilibrium) systems that have neither 'blown up' nor settled around an attractor into chaotic or some other order. These systems use up energy, are dissipative. The 'edge of chaos' is like the point before freezing and prior to the formation of a snowflake, a zone where emergent order can appear.

Emergence and Self-organization

Stuart Kauffman (1992), Ilya Prigogine, and others have described how near-chaotic systems self-organize. Surprisingly, even as entropy inevitably increases, more and more complex organization can develop. This was recognized by Alan Turing (in 1952!). Sally Goerner (1995, p. 26) writes, "... the growth of complexity (evolution) is an energy-flow rate phenomenon. ... self-organizations always increase the rate of energy transfer. ... [S]ystems ... go through a series of organizations and reorganizations as part of accelerating energy flow. Driven energy flow phenomena ... lead to a series of increasingly complex and intricately ordered patterns." This growth in organization does not contradict the second law of thermodynamics in the bigger picture; emergent new patterns in dissipative systems actually make transfer of energy more efficient and accelerate systems' rush toward entropy. Kauffman called this rising complexity 'order for free.'

Application to 'Intractable' Problems

Much about human life is difficult to account for, not just its evading self-steering and defying intervention. Certain problems are notoriously difficult and appear insoluble, 'complex,' 'perverse,' 'wicked,' or they 'bite back' (Tenner, 1996). It is useful to look for

cases precisely where older methods have failed; noted dynamics researcher and cardiologist Ary Goldberger (Goldberger and West, 1987) referred to problems “whose only apparent unifying theme was their ‘resistance’ to traditional models.” Refractory phenomena can become comprehensible, rational, and potentially amenable to modeling when we seek underlying NLDS processes using biological, psychological, and social models.

Nonlinear Dynamical Systems Themselves

Psychological phenomena manifest many of the characteristics of NLDS behavior in their unpredictability, mystery, changeability, robustness, adaptiveness, and fit to an environment; models explaining them, if they include nonlinear relationships, can be just plain simple and still account for the complexity in their behavior. Instances of cybernetic, opponent-process, and dialectical phenomena are widespread, with models relevant to creativity. One example is the dialectical interplay of lifelong strivings for individuality and interpersonal relatedness (Guisinger and Blatt, 1994). Such phenomena are amenable to modular, interacting, sometimes hierarchical models, combined LegoTM-style (Csete and Doyle, 2002). Aggregates are enriched by the complexifying consequences of nonlinear linkages.

Where’s the Nonlinearity?

Some nonlinear relationships and equations have already been mentioned. In general, adaptiveness, health, and wellbeing do not just follow in straight-line, increasing fashion from positive behaviors or virtues; even a medium is not always a happy one. Nonlinearities in psychology include Hebbian or Yerkes–Dodson-type inverted-U curves, discussed below.

Closed and Open Systems

Many current models assume systems that are self-contained, closed, isolated from other systems and the environment, as well as systems at what is called ‘thermodynamic equilibrium’ (which in some ways resembles stillness). In contrast, open systems exchange inputs and outputs with their surroundings. Our bodies, minds, even our genes transfer material and information to and from physical and social environments. This has important implications for the complex structures of our lives and work.

NLDS and Chaos Theory in Creativity and the Arts

The remainder explores how concepts from NLDS apply to core problems in creativity theory and research.

Time and Creativity

Creative productions necessarily appear dynamically, in motion and process; even an ‘instantaneous’ and spontaneous flash of insight unfolds over time. Creative activities have been described with stages of generativity and consolidation, incubation, intimation (Wallas, 1926), elaboration. ‘Regression’ and ideational fluency also unspool temporally. Productivity develops over a life span as works’ meanings and realizations are modified in cultural and historical contexts, the creator’s experiences and life stage, shifts in approach and technique. Performance explicitly includes time.

Genres and movements are pushed along by generations of participants. Cultural diffusion, innovation spreading, acquisition of craft and expert skill, all unfold in time, as do grasping a new idea or paradigm, trying it, and making it one’s own. New ideas, tastes, aesthetics, and movements can oscillate. Colin Martindale observed how fashion changes incrementally. A style goes (what is later called) ‘too far’ and a trend reverses. Neckties become wider, narrower, wide again. Swings can be understood with linear models too, but style dynamics may well involve chaotic rather than periodic attractors; the past does not repeat precisely and styles don’t return the same. Nostalgia, neo-this or that, irony, sentimentality, snark, defiance, youth reclaimed – all can nest in ‘retro.’ If ‘revival’ is a strange attractor, ‘old school’ is not quite the past. The leg warmers of 2019 look almost nothing like those of 2009, which themselves were similar but not quite the same as back in 1989.

Empirical creativity researchers, despite attention to process, have often taken static trait approaches; an example is treating divergent thinking as an individual capacity varying across individuals, rather than a within-person process of problem-solving.

Unpredictability: Sensitivity to Initial Conditions and Nudges

Unpredictability may be a hallmark of creative activity. The trajectory of where a work will go cannot reduce to simple, solvable equations. This is not to say that practicing and understanding creativity completely resists use of deterministic processes; however, technique is step-by-step, with results often not fully known beforehand. Zausner (1996) notes how artistic work is very sensitive to stimuli and speaks of the role of the ‘inconsequential’ in art, unpredictable but not random influences.

Near-Periodicity Without Strict Repetition

For something new, repeated jousts may be necessary. Freud noted the similarity of healthy versus unhealthy cycles of change, productive ‘working through’ versus self-defeating ‘repetition.’ Perhaps these represent strange or periodic attractors. Ego psychologists similarly described play as re-creating, aimed at mastery. Some view art as a working through of a psychological, aesthetic,

cultural, or technical problem. Sandra Russ and others comment on the inventiveness of young children's play, and the play-like, restitutive aspects of creativity in adults. Different attractors can illuminate whether play or creative labor solve particular psychological problems or represent neurotic stuckness.

Catastrophic Change and Bifurcating Systems

Bifurcation refers to transformation of a system or attractor into another kind, or a shift to a new regime of behavior (for example periodic to chaotic). Creative phenomena can exhibit near-regularity and then wild fluctuation. Things may be close to periodic in the innovation of normal science. In contrast, qualitative leaps in ideas or artefacts, revolutions and new movements, periods of insight or illumination, broken genres, and shifting paradigms all represent 'catastrophic' transformation. Breakthroughs may be numinous at times, when a creator seems 'possessed' by the work or the work 'creates itself.'

Zausner (1996) writes of creativity comprising subsystems bifurcating into new order. Chaotic systems can also settle back into stable attractor regions. Bifurcations may account for transitions from inspiration through consolidation and then to implementing a creative program, or shifting between riffing and editing, interleaving roles of performers, or how circus emerges from theatre and sport.

Chaos and Complexity in Creativity

Several characteristics of chaos are discernable in creative process and product. Process must avoid stasis, stagnation, premature closure, capture by fixed-point or limit-cycle attractors, and the strictures of a critical or imperious environment. Chaotic systems can demonstrate healthy flexibility, autonomy, and openness to new experiences. Neurologist Walter Freeman III famously wrote, "Chaos provides ... a deterministic 'I don't know' state within which new activity patterns can be generated" (Skarda and Freeman, 1987, p. 171). Frederick D. Abraham has spoken of 'self-organizational bifurcations,' observing that both chaos and instability can facilitate creativity. Late poet laureate Howard Nemerov spoke metaphorically of chaos as the primordial *order* before creation; Ben Goertzel, Ronald A. Finke, and others provide models of chaotic logic and cognition. Theorist and clinician Michael Bütz refers to not-strictly-speaking periodic psychic swings, with structure emerging from such chaotic behavior. The vicissitudes of different creative episodes can be viewed as patterned (phase) portraits of the positions and directions of multiple generative and expressive processes. When near some attractors, work remains within a genre, style, school, theoretical orientation, paradigm, convention, or norm. Style is a region around an attractor in a content-domain phase space (e.g., architecture, writing).

Attractors may also be useful for describing shifting artistic schools, or patterned themes and motifs within a single work or *oeuvre*. These include phenomena such as rhythm, repetition, progression, periods of 'decadence,' rediscovery of old ideas, recapitulation of themes within a work, entrainment and synchrony across different systems, narrative and non-narrative forms, multiple near-simultaneous discoveries, and revolution in the air.

Scaling, Symmetry, and Fractal Properties in Creative Work

Fractal patterns depict the self-similar ordering of trajectories represented around a chaotic strange attractor. Zausner (1996) observes how a person's creative periods appear self-similar, with successive inventiveness and reflectivity; this may parallel the correspondences between alternating mood states (including those in bipolar affective disorders) and creativity. Richards discusses the importance of experiencing and reconciling contradictory moods and mixed states. In addition, works of art – as opposed to reproductions and hack cover versions – are unique; fruits of creative process can have unpredictable or irregular yet not disorderly forms. An artist's different works are also self-similar and have 'family resemblances,' kinships reflecting the processes of their birth.

Fractals are similar (although not identical) at different scales of magnification. Their aesthetic qualities draw us in. People are attracted to waterfalls, beaches, and other things instantiating them. This is related to the draw of little things; Levi-Strauss (1966, p.23) wrote that, "all miniatures seem to have an intrinsic aesthetic quality." Small and complete, miniatures are important in creativity; symbol, song, statistical model, science toy, and mathematical notation are all miniatures. They point us toward scaling up or down, recursion, and fractals themselves. There is also tension between symmetry's sometimes inherent beauty and contrasting roles of imbalance, disequilibrium, intricacy, symmetry-breaking, facilitative entropy increase, and disorder. Creative people tend to prefer Barron-Welsh Art Scale figures that are asymmetrical and complicated. Nonidentical fractal similarity and nested recursive forms (as a play within a play) help reconcile these ideas.

Dissipative Systems: Does Creativity Occur at the Edge of Chaos?

This article discussed how dissipative or far from equilibrium systems can create new order and build structure, even as they accelerate a system's running down. Ruth Richards, Frederick Abraham, and others explore the importance of systems at the edge of chaos to creativity; creative work is dissipative. You can move a system away from equilibrium by increasing its energy temporarily. (Richards calls this 'Turning up the heat' to make multiple creative insights more likely; think of multiple popcorn kernels popping more often.)

Conditions that foster brainstorming may implement cognitive sets or workspace settings that move us somewhere between stasis (or periodic behavior) and (moderate-dimensional) chaos, as Csikszentmihalyi's 'flow' states lie between boredom and anxiety. Zausner (1996) describes artistic products as manifesting order; a work's uniqueness coalesces from dissipative structures. She also comments on potential disorder, with a fine line between 'breakthrough and breakdown.' Creativity and psychopathology

are sometimes close together; David Schuldberg (1994) speaks of both 'giddiness and horror' in the creative process. The edge of chaos also sheds light on transitional or 'liminal' phenomena, psychological or cultural in-between zones important in play, dreaming, interpersonal attachment, and psychotherapy.

Emergence and Self-organization

Zausner (1996) asks instructively, "Doesn't the artist have a plan for the painting?" A new work may be an emergent configuration rather than coming from planned progress toward a pre-imagined point. Creating involves self-organization, related to continually 'self-producing' and 'autopoietic' structures. Musical works, new theories, and novel solutions to coding problems can be viewed as emergent organization. This concept provides a window on how a great deal of new information is revealed, found, produced evaluated, and used by culture.

The Creativity Question as Intractable Itself

This article has discussed two forms of intractability. First, facilitating creativity is difficult. It may even be counterproductive to push for it; some speak of creative work as 'impossible' itself, at least in dry times. Secondly, the study of creativity has long tantalized philosophers, theorists, and researchers. One hint that it may be amenable to NLDS approaches comes from just this difficulty; remember Goldberger's dictum about hard-to-solve problems.

Nonlinear Models in Creativity

An understanding of potential nonlinear creativity models is important for grasping and comprehending, modeling, and fostering creativity.

Nonlinearity

First, where is the nonlinearity? What are relevant non-straight-line relationships? Richards and others have extensively demonstrated 'inverted-U' relationships between creativity and psychopathological characteristics, and this seems to hold for positive and negative affect as well. Simonton, David Harrington, and others also comment on nonlinear relationships among creativity variables.

Fig. 3's model can provide a toy demonstration. (Remember that its nonlinearity comes from the 'hard' nonlinear spring in the middle.) To see this, we can define its horizontal (x) axis as ranging from 'inner focus' on the left to 'outer focus' toward the right. When one block is moved and released, they trace oscillating paths depicting intrapsychic delving, incubation, woodshedding, potential access to 'primary process' material at the left, with environmental immersion, making the work, performance, dissemination, and suffering critical feedback all toward the right. A strange attractor in a phase-space rendition of the motion could signify a region of constrained novelty, spinning ideas converging and diverging without repeating exactly; the system could also settle into repetitive, ho-hum patterning.

Open Systems and Creativity

Creativity is environmentally situated; perception and action function at the interface between organism and environment. External nature, so fractal in itself, has much to teach and inspire. Similarly, the creator engages somewhat, whether personally or not, happily or not, with the physical and social worlds, materials and audience. Engagement, ongoing, embeds proceedings in time.

Evolutionary Epistemology, Emergent Order, and Creative Processing

Evolutionary epistemology studies how new knowledge develops and accumulates, analogously to biological structures' evolution through Darwinian natural selection. Psychologist Donald T. Campbell (1960) presented a useful account of creative cognition, suggesting that creativity starts with a wide variety of ideas attained relatively 'blindly' (although not by mere chance). This initial multiplicity of ideas is analogous to the diverse variety of biological forms in Darwinian evolution, introduced into the genome by random mutation and other factors. Diverse ideas are then evaluated and retained or discarded according to 'quality' or utility; this corresponds to the selection and transmission of heritable biological traits on the basis of their 'fitness.' It is fruitful to pursue Campbell's model further and explore how mutation, selection, and adaptation apply to memes (Dawkins' term, itself one) in creativity, how emergence provides new genotypes, then phenotypes, for selection to act upon.

Complex Systems, Creativity and Evolution

As noted above, dissipative systems can create emergent new order 'for free.' This increasing organization is not just possible but favored with ever-increasing entropy. This holds for the recombinations and expressions of basic genetic mutations, two phenomena involving dissipative biological processes. The products of this morphogenesis are then the raw materials for a next round of selection of both biological structures and ideas; the order coming from the edge of chaos contributes additional variation for evolutionary selection to retain or discard. Effects of individual, granular mutations interact, combine, and unfold in gene expression within the phenotype, and through environmental selection, as well as over lengthier evolutionary history. Emergent

forms amplify how diversity is generated and expand where variability comes from; this includes epigenetic effects, as environmental information alters the expression of genes.

The rich diversity of concrete products, behavior, or ideas is also potentially magnified through the across-time interactions of multiple small variations in ideas. In creative activity, many basic novel items (memes) interact and combine nonlinearly to produce more novelty, an ever vaster variety of forms to select or throw away. The modular, combinatory, and dynamic properties and principals undergirding variation, expression, and selection augment the processes of both biological evolution and creativity.

Sleep and Dreaming

An example of multiple and recursive looping in human evolution and creativity involves sleep and dreaming. Humans spend much more time in REM sleep than any other primate. Neuropsychologist [Matthew Walker \(2017, pp. 75–76\)](#) proposes that increased dreaming was important to the creative leaps in human culture leading to modern *homo sapiens*. He notes primate ancestors nesting in trees spent much less time in REM sleep, perhaps to minimize accidental falls. However, REM sleep is extraordinarily creative. “The second evolutionary contribution that the REM-sleep dreaming state fuels is creativity. ... REM sleep ... takes ... freshly minted memories and begins colliding them with the entire back catalog of your life’s autobiography. ... we can appreciate ... a classic, self-fulfilling positive cycle of evolution. Our shift from tree to ground sleeping instigated an ever more bountiful amount of relative REM sleep” He adds, “from this bounty emerged a steep increase in cognitive creativity, emotional intelligence, and social complexity.”

Techniques to Increase Variability and Foster Creativity

Combinations can be formed in many ways, including: Juxtaposing and mixing distinct or diverse elements, sliding unrelated concepts past each other, examining match, mismatch, blends, and interesting features, noting when contrasts create conceptual connections or conundrums, and discarding unproductive or unpleasing correspondences (part of ‘selective retention’). Superimpositions and combinations can be casual, constructed as non-hierarchical collage, even force-fit. They may display playful, hostile, or destructive, attitudes toward more ‘sensible’ or acceptable agglomerations. They do not strive for superordinate categories or top-down chain of command. They have relationships with more developmentally prior concepts, akin to Piaget’s preoperational thought and Vygotsky’s thinking in complexes, something noted by Richards. Varieties of superimposition, accretion, assemblage, Fabulized Combinations on the Rorschach, apparent synesthesia – these all represent additive and multiplicative combinatory experiences and behaviors. [Rothenberg’s \(1979\)](#) homospatial and Janusian thinking describe such routes to new ideas.

Creative cognition later ‘channelizes’ into ‘creodes,’ evolutionary biologist [C. H. Waddington’s \(1957\)](#) term, deepening valleys in landscapes of developing ideas. Periods of normal science, mature and then stale genres, correspond to valleys. Similar models have been constructed with neural network and other techniques to simulate perception, thinking among people with schizophrenia, interpersonal and psychotherapy process ([Pincus, 2001](#)), leadership and decision-making ([Guastello, 2010](#)), and attitude formation ([Vallacher and Nowak, 1994](#)).

A Dynamical Systems Program for Creativity

Creativity research will benefit from even more consideration of dynamical systems approaches and how they can illuminate originality. New ideas and techniques can help, based on theoretical and empirical models that include time as a variable and contain curvilinear relationships or interacting variables. How does a ‘remote associate’ on Mednick’s test emerge or converge? What is the trajectory of an artistic career? What are transitions from incubating to elaborating, from boredom or anxiety to ‘Flow?’ How does a ‘creative crisis’ resolve, or not? How to do the impossible and make art?

Recent research shows that – for very complicated problems (such as optimizing with many, many constraints) – inattentive, background, off-line, non-focal, parallelized computation (and ‘sleeping on it’) serve extremely well. Nevertheless, a creative adult’s improvised or indirect approaches to new problems represent incremental strategies, practical wisdom but not theory. Real things vary too much for relentlessly complete on-line processing or exhaustive categorization.

This speaks to the key role of distributed, peripheral, and low-level (versus executive and top-down) processing, and the use of heuristics, inexact procedures without guaranteed results that are often extremely useful and efficient. We would often best engage in ‘satisficing,’ instead of ‘optimizing’ or ‘maximizing’ (Herbert Simon). New understandings come in approximations and increments rather than dropping, guaranteed, from formulas. We can provide guidelines and procedures for creative brainstorming, but not a cookbook for ideas themselves. Indeed, if we found such a cookbook we might not call its results creative; this issue is coming up in current discussions of whether algorithms derived using Artificial Intelligence (AI) can be creative.

Making sense of our own lives, planning, steering, and ‘rational choice’ are all approximate, sometimes irrelevant, and they contain blind spots. Living as we do through everyday language, we use incomplete but handy views of the world, innumerable daily instances of Richards’ (2017) *Everyday Creativity*. Heuristics have nonlinear effects and interactions, and we can only see their results after the fact. Thus, our attainments are not easily decomposable into components, and we can’t play them backwards. [Tobi Zausner \(1996\)](#) comments on the irreversibility of painting, situating it outside of Piagetian formal operations and squarely as a dissipative system. Because chaos is involved, even SCS produce complex outputs. We inhabit big ideas, often gracefully, and grapple with existential concerns; life’s practical crafts are humble and hands-on, productively using ‘simple rules.’ This does put limit on social engineering and thankfully prohibits a truly totalizing fix on the good life.

Yet, this does not limit what is possible in everyday life. Our human and natural world is determined yet unpredictable, complex and varying but also organized, changeable and sometimes shocking. It is self-similar day to day, and sometimes very beautiful. We must sideline perfection to embrace and create the rough-cut splendor and daily miniatures of our local worlds.

At the same time, climate change presents macro, complex systems problems that require creative solutions for the survival of our nonlinear and dynamic ecosystem, and quickly too. We are upon urgent times; what can we learn from the extinctions of the past? As we act locally, create and improvise we must, with an eye on the big picture, quickly and carefully.

Introduction

The assortment of organizations that serve society, providing services that empower the disadvantaged or provide charitable assistance, are important societal institutions. However, countries around the world offer different terminology to define the work of organizations established for public benefit.

The term, Non-governmental Organization (NGO) is a ubiquitous term that refers to local, national, or international organizations or associations that reside outside the business and political realms. The definition was initially established in the United Nations Charter and refers to organizations that may be consulted by the UN as it proceeds with its operations. The term, International Non-governmental Organization (INGO) is also popular and refers to the various groups that have organized to pursue goals that transcend national boundaries (Boli, 2006). Amnesty International, Oxfam, Human Rights Watch, Médecins sans Frontières (Doctors without Borders), Save the Children International, and CARE International all represent INGOs.

Public Benefit Organizations, commonly described as charities, provide support for relief of poverty, caring for the sick, and promote other public benefit endeavors. Such organizations are similar to NGOs and INGOs because they come from the same tradition of philanthropy. History records that the era of European Enlightenment included the establishment of philanthropic organizations that transformed society. Even earlier, religious organizations supported benevolent actions. Accounts of philanthropic organizations also date back to 13th century China (Davies, 2013).

In the United States, organizations that provide public benefit are generally referred to as nonprofits. While US organizations share some of the attributes of the Public Benefit Organizations in other countries, the nonprofit sector in the United States has some distinguishing features.

US Nonprofit Sector

When considering the United States economy, it is important to understand the three sectors that impact the health of the nation. Each plays an integral role in contributing to a vigorous and vibrant society.

The Public or State Sector refers to federal, state, and local governments. These entities have the authority to pass legislation to support the general welfare of citizens. Government is largely funded by a variety of taxes and fees that are paid by citizens and other tax-paying organizations.

The Business or For-profit Sector is made up of organizations and individuals that run profit-making ventures that are only partially subject to public sector control. The private sector generates profits from operations, and these profits fund the Public Sector through taxes.

The third division of the economy is termed the Nonprofit Sector. A variety of organizations—including public charities and foundations—are part of this sector that is unique in its mandate to provide public benefit through mission-based efforts. Recognizing that the nonprofit sector is not as well-known or understood as its mightier cousins, it is important to be familiar with how this sector operates and why its health is essential to the US economy.

Nonprofit organizations provide programs and services that support a self-defined mission. An organization's mission represents its public responsibility to improve society through implemented programs and other activities. While these organizations must demonstrate fiscal prudence in operations, they are not driven by a profit motive that is customarily apparent in the for-profit sector. Rather the mission represents the nonprofit's overarching goal. This means that the nonprofit sector strives to accomplish a double bottom line where success is measured by both financial and mission effectiveness.

Additionally, while nonprofits are known as businesses with public missions, they are funded in distinctive ways. Individual, foundation, and corporate donations are common funding mechanisms. Nonprofits also receive grants and contracts from government agencies and proceeds from the sale of goods and services to their clients and others.

Another characteristic of the sector is that public charities in the US are exempt from many taxes. They generally don't pay income tax, and, in some cases, they are exempt from property, sales, and value-added taxes. This means that governmental agencies forego tax revenue to promote nonprofit operations. Another unique feature of the nonprofit sector is that individuals and organizations that make donations to qualified nonprofits generally receive tax relief for those donations.

The size of the US nonprofit sector is most often measured in terms of donations that come from individuals, foundations, and corporations. In 2017, donations exceeded \$400 billion ([Giving USA 2018](#)). Another measure of size considers the number of organizations that are classified as nonprofits. In 2013, the IRS had registered a total of 1.41 million nonprofits ([McKeever, 2018](#)).

Nonprofits are an important contributor to the economy. In fact, eighty-six percent of wealthy donors have confidence in nonprofits to solve social problems—more confidence than in the federal government or other public sector participants ([U.S. Trust, 2018](#)).

The Three-Failures Theory emphasizes the interrelated structure of the US economy. The theory, described by [Steinberg \(2006\)](#), explains how the three sectors (Government, For-profit, Nonprofit) respond to failures to deliver appropriate services to applicable constituencies within society. The three sectors constitute a circle where each member responds to the contract failures of its neighbors. When failure to provide adequate quality and quantity of services occurs, one of the other sectors steps in to provide the required assistance ([Steinberg, 2006](#)).

For example, educational institutions (nonprofits) need computers for instructional purposes. However, not all schools have funds to buy computers from the for-profit sector. When this happens, either government steps in to provide computers to schools, or for-profits arrange to donate the necessary equipment. Another example is when nonprofits give meals and groceries to individuals to provide necessary additional food to augment the government's Supplemental Nutrition Assistance Program. Also, many nonprofits devote their time to missions that involve environmental agendas—stepping in to protect the environment where government and for-profit organizations have failed. More recently, for-profits have been investigating developing private insurance alternatives for their employees because they view government alternatives as both inadequate and expensive.

The interrelatedness of the three structures signifies that all sectors play noteworthy roles in creating a successful society. While government and business sectors are recognized for their important roles, the nonprofit sector also contributes much to society, which would be significantly less effective, caring, and vibrant without it.

Program success enhances mission accomplishment in the Nonprofit Sector. Programs may be varied based on the nonprofit mission, but whether a nonprofit provides social services to its clients, conducts research to find cures for diseases, or encourages voter registration, the programs provided must be effective. Additionally, funding mechanisms in the nonprofit sector are inherently unstable because individuals, government, and industry can change giving priorities which reduces the sector's collective ability to operate cost-effectively and accomplish respective missions. Therefore, with survival at stake, nonprofit leaders must recognize that to ensure success, they must develop creative programs to support mission achievement and put in place innovative fundraising mechanisms to finance their operations.

The economies of other countries don't necessarily have the same interrelatedness as seen in the US. In some cases, Public Benefit Organizations are largely funded by government, making solicitation of individual donors and corporations nonessential. Different organizational structure and tax laws also make the US model distinctive. However, all Public Benefit Organizations around the world can benefit from creativity. The following section applies equally to US nonprofits, Non-governmental Organizations, and International Non-governmental Organizations. Creativity transcends national boundaries and innovative outcomes are essential to improve circumstances around the world.

Creativity in Nonprofit Programs

Nonprofit programs use many strategies and processes that are familiar to researchers in creativity. Following are examples of creative programs that demonstrate impact and can be associated with specific creative approaches. The examples have been grouped by creative strategy.

Combining Disparate Ideas

This strategy involves looking for relatedness in ideas that seem unrelated. In general terms, the strategy involves combining alternate perspectives that can provoke novel connections between ideas that come from different fields—something that can be described as having an unexpected twist ([McCaffrey, 2012](#)).

Jim Fruchterman knows how to use alternative perspectives to enhance creativity. He is the founder of Benetech, a Silicon Valley nonprofit. He is also a MacArthur Fellow—one of the individuals awarded the prestigious MacArthur Foundation award for creativity. Since 1989 Benetech has been developing and providing software to help other nonprofits creatively meet societal needs. In an early project, Benetech demonstrated the power of combining disparate ideas.

Fruchterman wanted to solve a problem for individuals who have difficulties making use of printed books. This group of individuals who may have visual impairments, a variety of learning disabilities, or limited mobility are not able to use printed material in the traditional way. As he considered the problem, Fruchterman recalled that in one of his most exciting engineering classes at Caltech he learned how to design technology that would allow a computer to distinguish various sorts of military targets (e.g., different types of military tanks). The weapons systems in his class project could direct munitions to strike specific targets. Considering his goals to provide access to books for those with disabilities, Fruchterman recognized the parallels in the unrelated projects. He reasoned that if computers could distinguish between military targets, they could also distinguish the shapes of letters (Benetech, 2019).

Using the same basic technology, Fruchterman developed a reading machine that used the tank-targeting technology. Despite the obvious differences (in size, shape, and purpose) between military tanks and letters, Fruchterman was able to understand that the same computer technology could solve both problems. By seeing the relationship between the two problems, he was able to envision new uses for the tank-targeting technology. Fruchterman went on to create Bookshare, a library of textbooks, bestsellers, and children's books. In this novel version of a library, books are read to individuals who cannot utilize traditional paper editions (Hennesy, 2017).

Another group of nonprofits knows how to combine ideas to make a difference in the lives of seniors in San Diego County California. North County Senior Connections in conjunction with Dreams for Change, Interfaith Community Services, the Jacobs & Cushman San Diego Food Bank, and funded by the Rancho Santa Fe Foundation incorporate two important aspects of healthy senior living—nutrition and socialization (Rancho Santa Fe Foundation, 2019).

The collaborating nonprofits serve the dual needs of low-income seniors in San Diego County with both healthy meals and important opportunities to socialize. The nonprofit collaboration distributes freshly prepared meals from a mobile food truck, appropriately named Thyme Together. To augment the food service, community members provide lunch time activities that inform and entertain the seniors (Rancho Santa Fe Foundation, 2019).

This mobile collaborative of nonprofits succeeds in a number of ways. Not only do participating seniors choose from a full menu of nutritious lunch options, they also can pay for their economically priced meals (generally \$2 a meal) with CalFresh benefits. CalFresh is the local supplemental nutrition assistance program. Furthermore, the efforts of the collaborating nonprofits provide a mobile senior center that meets the seniors in their communities, allowing them the opportunity to enjoy social interaction.

Big Picture Thinking

Another creative way to confront a problem is to consider the larger context in which a challenge is contained. This strategy involves taking a metaphorical step back to better understand the parameters and background of a situation. Insights from this change of perspective can provide novel answers to a problem (Sternberg, 2006).

In 2009, Dr. Teresa Smith founded the nonprofit, Dreams for Change, to meet the needs of individuals and families who had been adversely affected by the financial downturn. Dr. Smith and her colleagues from San Diego State University's School of Social Work and California Western Law School collaborated to produce a novel solution based on stepping back to consider the big picture surrounding homelessness. Recognizing that homelessness is a complex issue, the group decided to concentrate on one part of the problem. They considered the situation where individuals or families had been forced to leave home and seek permanent shelter in their vehicles. When this happens, not only does the vehicle provide transportation to work for adults and school for their children, but also the car is used for nighttime accommodation. Often its last and most valuable asset, these vehicles represent a family's bridge between poverty and homelessness (Dreams for Change, 2019).

Dreams for Change created The Safe Parking Program to provide safety and some stability for those living in their vehicles. Clients are welcomed nightly at one of two safe sites. Staffed by case managers and volunteers, the program can accommodate seventy families each evening. In addition, the nonprofit provides transitional services to help clients find permanent housing, employment, training, and emergency support to stabilize their circumstances. These services have the goal of not only stopping the slide into homelessness, but also helping participants gain skills and income that will lead to self-reliance (Dreams for Change, 2019).

By understanding the needs of those who must sleep in their cars, Dreams for Change has been able to keep individuals and families safe and prevent a further decline in their economic stability. The organization provides its struggling clients with an innovative strategy—a secure home in a car until other options are found. This pioneering program creatively supports its clients and helps them maintain their independence. This example of program creativity supports the clients of Dreams for Change and effectively addresses one aspect of homelessness.

Doniece Sandoval, founder and CEO of nonprofit Lava Mae, also provides an example of how big picture thinking can contribute to solving specific social issues. Lava Mae addressed the fact that those who are homeless do not have access to hygiene alternatives. Without ways to keep clean, the homeless have no way to change their situations because a lack of hygiene makes finding a job or even social interaction with others a major obstacle. A lack of hygiene not only contributes to homelessness, but also adversely impacts human dignity. To address this problem, Sandoval created opportunities for those without resources

to access showers and toilets by repurposing retired transportation buses to serve as mobile shower units. These units were connected to fire hydrants. More recently commercial shower units have been employed ([Hughes, 2017](#)).

Lava Mae augmented shower and toilet services with pop-up care villages that provide medical and dental services. Bringing the services to the people where they congregate has helped promote what Sandoval calls radical hospitality—the notion that how you provide a service can be just as important as the service itself. Sandoval founded Lava Mae in 2013 and since then has served more than 15,000 individuals. Delivery of similar services has expanded to Los Angeles and Oakland ([Lava Mae, 2019](#)).

Recognizing the importance of hygiene and acting to provide alternatives for those who are without ways to keep clean represents a big picture understanding of homelessness—one of the most intractable problems that society faces. Lava Mae's response to the challenge represents an innovative way to ease the problem.

Rejecting Inadequate Paradigms

Paradigms—concepts and theories that inform various fields of endeavor—provide structure and substance within most disciplines. Moreover, paradigms specify standards for what approaches and methodologies are considered legitimate when contributions are made to a field. However, assumptions that inform paradigms can become outmoded or in other ways insufficient to support and bound a field. When this occurs, original perspectives and assumptions may need to be replaced by creative alternatives that can expand insights. Fortunately, Dr. Victoria Hale, a recipient of the MacArthur Foundation creativity award, was not willing to accept for-profit sector paradigms that recognize a limited number of business models in the economy. Her efforts provide a good example of how creativity can impact paradigms.

Dr. Hale received a PhD in pharmaceutical chemistry and is a social entrepreneur in the pharmaceutical industry where she develops new drugs and medical solutions. As Dr. Hale considered how she could help the poorest of the world get the medical attention that they require and deserve, she recognized that the for-profit model that generally requires a solitary pursuit of profit was simply not an effective way to approach the problem. As a result, she created a nonprofit pharmaceutical organization ([Hennessy, 2017](#)).

Over time, Dr. Hale realized that this nonprofit model could not support all of her ambitious goals. While it was sufficient to financially support nonprofit research and the creation of drugs, it did not allow the organization to actually serve patients. Acknowledging the shortcomings of the nonprofit model, Dr. Hale began her search for a new hybrid business model that would help her achieve all of her goals ([Hennessy, 2017](#)).

Dr. Hale solved her business problem by partnering with a well-respected for-profit business that licensed her medical products for sale in the lucrative US market. Her organization receives a royalty payment that supports further drug research and allows her organization to distribute the medical devices to poorer patients around the world ([Hennessy, 2017](#)).

Creating a hybrid organization takes advantage of aspects of both the nonprofit and for-profit sectors. Dr. Hale has creatively bridged the sectors to establish an organization that supports her mission and provides ongoing funding for drug development. In rejecting traditional business models, she established an alternate business paradigm that creatively and effectively serves her social goals.

Another creative entrepreneur disrupted a paradigm associated with hospital eateries. Hospitals are not known for their culinary expertise and while patients have to eat hospital food, generally few visitors willingly dine in hospital cafeterias. Helen Doherty, recognizing this paradigm, decided to create another standard for hospital diners. In her role as Director of Dietetics, Doherty eschewed the low bar goal of edible food and created a different dining experience at Massachusetts General Hospital in Boston ([Ross, 2002](#)).

Doherty's goal was to create food service outlets that were so superior that they would bring non-patients to the hospital for meals. Her efforts were rewarded. She received the 1999 Restaurateur of the Year award from the Massachusetts Restaurant Association. Doherty was the first woman and Massachusetts General Hospital was the first institution to receive the award. In April of 1999 the cafeteria and other hospital outlets were preparing and serving food for about 900 patients and 13,000 non-patients daily ([Ross, 2002](#)).

While Doherty's culinary goals improved the overall dining alternatives for hospital patients, staff, and visitors, she also helped a specific patient population. Massachusetts General Hospital is associated with the Dana-Farber Cancer Institute. Doherty created a special café for cancer patients being treated at the hospital. Knowing that the effects of some cancer treatments can suppress appetite, she designed a special menu of small portions that were healthy and appealing for customers ([Ross, 2002](#)).

In rejecting the conventional wisdom that hospital food is customarily unappetizing, Doherty transformed a model in a common industry, creating a new standard for food service. She demonstrated that new paradigms can eclipse outdated standards when an individual activates creativity and sets higher expectations.

Creativity in Nonprofit Funding

The second area where nonprofits require creative strategies is in fundraising. While there are traditional ways of raising funds that have endured and are likely to exist going forward, nonprofits have the opportunity to consider creative fundraising alternatives that can attract donors who seek a newer approach to supporting organizational missions. Matching donors with their preferred giving

strategy can increase donations and inspire allegiance to a cause. As creative alternatives become available, nonprofits need to take advantage of opportunities to participate in these innovative options.

Social Finance

Several new funding alternatives are available to donors. The overarching name for these creative strategies is called Social Finance (Shah and Costa, 2013). Under this umbrella of strategies are new methods of grant-making that favor social innovation and public-private partnerships. Also described as social impact bonds or, more generally, pay for success contracts, they represent novel ways to tap the capital markets for nonprofit funding.

In general, innovation funds address the shortcomings of traditional government grants that often provide funds for only a limited time—a year or two and are not renewable (Shah and Costa, 2013). In particular, The Social Innovation Fund, created in 2009, takes a longer-term approach and adds an element of entrepreneurship to the process. It seeks strong organizations that have experience finding and funding social services nonprofits. These intermediaries assess individual nonprofits, choosing the most innovative programs in which to invest federal funds. Grants are made in larger amounts and are available for up to five years. Furthermore, the federal funds are leveraged because intermediaries are expected to match the federal grants with equal dollar contributions from non-governmental sources.

There is a three-fold benefit to these creative funding programs. The intermediaries are skilled at finding the most innovative programs available within the nonprofit sector. Also, by carefully monitoring the programs, the intermediaries observe program progress and are able to provide additional funds over time for scaling those programs that are most successful. Finally, the requirement to contribute private philanthropic dollars in addition to public funds provides leverage and increases the amounts available to support nonprofit programs.

Nonprofits can seek another innovative source of funds from investors. Dubbed Pay for Success funding, these innovative contracts are also called Social Impact Bonds (SIB). Shah and Costa (2013) noted that these instruments are not actually securities in the traditional sense but are innovative financial agreements that require public sector money to be paid to investors if agreed upon outcomes are met. Thus, government money does not flow to failed projects. This fact turns traditional government funding on its head—no risk of failed projects and payment only in circumstances deemed to be successful. Palandjian (2017) summarized the innovative nature of SIBs as a transfer of risk from the public sector to the private sector.

The players in this model are investors, independent evaluators, nonprofit service providers, and government officials. The investors pledge to achieve a particular goal and agree that the government is not responsible for payment unless an independent evaluator confirms that the goals of the contract have been achieved by the nonprofit service provider. If independent evaluators certify that goals have been achieved, only then do government officials transfer funds to investors (principal amounts plus an additional amount of money to compensate for the risk taken by the investors) (Shah and Costa, 2013).

The first Social Impact Bond project was conducted at Peterborough Prison in the United Kingdom. The goal of the project was to reduce recidivism in prisoners that had been incarcerated for less than a year. The project began in 2010 and final assessment of the venture occurred in 2017. The project assessment calculated that the average reduction in reoffending was 9% in the two cohorts involved in the study. Baseline improvement in the SIB contract required a 7.5% improvement so the result of 9% triggered a payment for investors (Anders and Dorsett, 2017).

Success in various projects funded by Social Impact Bonds continues to be assessed. However, as Costa and Tomasko (2014) pointed out, the contracts are complex. They require cooperation between government agencies, nonprofits, investors, and intermediaries. The cooperative nature of the contracts represents an innovative approach that signals that collaboration is an important practice in such situations.

This Pay for Success model has also taken hold in the United States. There are 17 projects underway that involve \$200 M in capital (Palandjian, 2017). It is likely that this innovative structure of financing will expand and evolve as organizations continue to innovate.

Tax Credit for Corporations and Individuals that Fund Education Initiatives

Another innovative collaboration has been created in the state of Georgia where individuals or corporations may claim a dollar-for-dollar tax credit on their state income tax returns in exchange for a donation to the Innovation Fund Foundation (Georgia's Innovation Fund, 2019). In this arrangement, the Innovation Fund Foundation serves as a nonprofit intermediary that controls the funds collected and uses the funds to provide grants to public schools in the state. The focus is on providing funds to improve student achievement. Priority is given to serving schools with low performance ratings (Georgia's Innovation Fund, 2019).

This state initiative represents a partnership that invites individuals and corporations to join forces in a particular poverty-fighting initiative. The state is providing an exceptional opportunity for donors to receive a tax credit that goes beyond the customary tax deduction of a typical donation. Moreover, the state is only offering this opportunity for donations to an educational fund—prioritizing this sector over others. The state of Georgia's initiative is timely as data from the 2018 U.S. Trust Study of High Net Worth Philanthropy reported that the percentage of high net worth households in the United States that donate to educational charities (K-12) has declined from 33% in 2015 to 24% in 2017 (U.S. Trust, 2018).

Abundance Mentality Leads to Collaborative Fundraising Efforts

Conventional wisdom in the nonprofit sector contends that active donor and potential donor contacts should be carefully guarded and not disclosed to other nonprofits that share the same mission. The logic is that the potential for donations is limited and sharing information is likely to reduce the possibility of gaining a share of potential funding. Believing that the fundraising pie is limited leads to the conclusion that one nonprofit's gain means a loss for another. Like much conventional wisdom—so called wisdom that is accepted as fact and not scrutinized for veracity—this zero-sum logic should be questioned.

Choksi-Chugh (2018), Executive Director of nonprofit San Francisco Baykeeper, believes the nonprofit fundraising pie can expand. She collaborated with multiple nonprofits concerned with preventing and reducing environmental destruction in San Francisco Bay to test the idea. The nonprofits planned a unique on-the-water fundraiser and each invited donors and potential donors to attend the joint event. Following the event, a case study, prepared jointly by the participating nonprofits, was presented to potential donors. Funders were invited to participate in a joint project developed by the collaborating nonprofits or to invest in various parts of the project. Funders shared their appreciation for the collaborative approach and to date one new grant has been received by San Francisco Baykeeper and an additional funder has increased support. Other partners in the collaborative effort also received new grants. One funder even provided a grant to be shared equally by the collaborative (Choksi-Chugh, 2019).

More important than the actual monetary gift, the nonprofit sector now has evidence that collaboration between like nonprofits can benefit the sector. Rather than accept the conventional wisdom that the nonprofit sector operates in an environment of scarcity, there is now a growing sense that collaboration represents a new and creative way to operate and is a step towards eliminating the silos so often present in the nonprofit sector.

Commercial Earned Income Opportunities

Donations and grants are traditional fund sources for nonprofits. However, many nonprofits participate in earned income opportunities because such operations offer alternative funding that many deem more predictable than a revenue stream based entirely on donations. The idea is that mixed revenue streams provide a more predictable income for nonprofit organizations and prevent the potential of a starvation cycle of donations only. Therefore, organizations that manage earned income opportunities are considered more sustainable.

Some nonprofits consider commercial earned income opportunities to be a new strategy for gaining operational funds. However, nonprofits have been participating in earned income opportunities for decades. For instance, the ubiquitous gift store through which a visitor must exit most museums represents an example of attempts to generate earned income for the nonprofit organization.

Most often side ventures are intentionally created to align with the organizational mission. In the case of the museums, the products sold in the store generally relate to the educational mission of the museum. Nonprofits choose this approach to make sure that proceeds remain tax-free to the organization. As long as a nonprofit's income is considered to be related to its mission or exempt purpose, the IRS will not tax the proceeds (Gries, 2017). The IRS specifies additional exceptions for volunteer operated endeavors and those run for the convenience of staff, members, patients, or students (Chan, 2011).

For decades the Girl Scouts have successfully related their activities selling cookies to their mission of promoting leadership and business education (Hawthorne, 2018). Nonprofits could consider emulating the Girl Scouts by identifying and creating opportunities that represent additional income. Such innovative ideas could help nonprofits become more sustainable while staying within IRS guidelines.

Foundations have taken even more audacious steps by designing investment strategies that provide lucrative returns to augment their traditional funding streams. For instance, acting more like venture capitalists, some large foundations, rather than making grants to nonprofits, are investing in for-profit start-ups and even publicly traded companies hoping to provide game changing answers and revolutionary treatments for diseases (Wieczner, 2015). The Cystic Fibrosis Foundation's investment in a for-profit company resulted in both an advancement in disease treatment and also royalty rights to the drugs created. Moreover, the Bill and Melinda Gates Foundation has regularly increased its program funding through investment. Key is making sure that the IRS regards the returns on the investments in the same way that charitable donations are viewed. As large foundations introduce creative approaches to mission accomplishment, it is likely that such additional opportunities will positively impact and stabilize sector revenues.

Crowdfunding

Another development that supports nonprofits is the concept of crowdfunding. Crowdfunding is a generic term that represents the efforts of individuals and organizations to raise revenue from a large number of people over the Internet. The earliest crowdfunding schemes involved raising money to fund a project or venture in the for-profit sector. The funds received through Internet portals serve as an alternate form of finance for these enterprises, giving them access to capital and increasing the pool of investors. Venture capital and debt funding options are both available.

Similar to the for-profit model, nonprofit crowdfunding requires contracting with a fundraising platform on the Internet to provide opportunities for individuals to donate money to specific activities. Mirroring efforts in the for-profit sector, nonprofits

are using the same strategies and social media platforms to promote their specific programs or causes. Like other fundraising approaches, crowdfunding depends on an emotional appeal to potential donors.

The creativity of crowdfunding is two-fold. It uses social media to tap a large number of potential donors who are contacted through various online platforms and are connected to donation portals. Campaigns can go viral and attract donations from multiple diverse online communities—many that may not have previously been aware of the specific nonprofit or its mission. In addition, the ease with which donations can be made adds to the success of the platform.

The bottom line is that social media has taken hold and funding for nonprofit projects on the Internet is here to stay. Additionally, technology advances are likely to increase the number of creative alternatives that are available, so nonprofits need to be ready to take advantage of new opportunities.

Due to differences in legal systems, tax laws, and even societal norms, the fundraising strategies described in this section may not be licit or even feasible in all countries. However, innovative strategies such as social finance are likely to become worldwide standards in the future. Tax incentives and earned income requirements in individual countries also vary so it is important to consult local tax laws before trying to mirror these strategies. However, the concept of abundance transcends borders and crowdfunding is already employed internationally.

Conclusion

Organizations created for public benefit are called by various names around the world. However, no matter what name is customary, these organizations provide important structure to civil society and are pivotal in constructing solutions to intractable problems that occur locally or span international boundaries. In particular, the nonprofit sector is pivotal to the economic strength of the United States. Not only is the sector large and growing larger, the missions that the sector fulfills are of increasing importance. The nonprofit sector will continue to provide needed services to clients, and nonprofit missions will continue to help society fulfill its contract with its citizens. Keeping the sector healthy is of utmost importance.

One of the ways to promote a healthy and vibrant nonprofit sector around the world is to encourage talented leaders in the sector to express their creativity. Leaders who are trained to look for creative strategies must introduce innovative concepts and initiatives that can be integrated into the daily operation of public benefit organizations. In particular, developing creative programs that answer client needs and provide overall impactful service are required. Furthermore, these programs must be characterized not only by innovative design, but also innovative delivery.

Creative funding mechanisms must also be evaluated and incorporated so that the sector can be funded. Nonprofits need to minimize their time fundraising so that they can concentrate on mission achievement. Fundraising needs to be a means to an end, not an end in itself.

Since creativity can be activated and developed using multiple strategies and processes, the goal of nonprofit leaders should be to promote creativity in all organizational processes. Any organization with a social mission should consider engaging in ongoing dialogues about creativity to be sure that creativity is valued. Moreover, leaders need to understand that a free-flowing dialogue about creativity can translate into specific outcomes and encourage a cycle of creativity that can boost the overall impact of a specific organization. However, key to this creativity movement is leadership. Public Benefit Organizations around the world need to employ individuals who value creativity and demonstrate a commitment to introducing and supporting innovative approaches in all facets of an organization. While journeyman employees who are reliable and competent are needed in the sector to implement creative agendas, only creative visionaries can lead this important sector to greater achievement.

Glossary

Coherence The quality of being logical and consistent, of forming a unified whole. Usually based on a linear pattern, narrative coherence is necessary to fiction writing but not to all forms of creative writing.

Fiction In narrative literature, fiction refers to a form of prose that describes or reveals imaginary events and people. Fiction is a delivery system of meaning and should not be confused with the notion of falsehood or the conversational juxtaposition of fact versus fiction.

Implied author What the reader infers about the author from how a piece of fiction is written. Distinct from the writer and narrator, the implied author (the authorial character) is a construct, or mask, that corresponds only in degrees to the human writer's intentions, personality, beliefs, etc.

Narrative In fiction writing, the sequence in which the story and plot are revealed.

Narrative tense The grammatical tense of the text. Though present tense (do, say) is used effectively in many novels, the most common and traditional tense is the past tense (did, said), in which the story and events of the plot occurred at some time prior to the narrative delivery.

Narrative voicing The perspective or viewpoint (or mode) of the narrator's presentation, usually written in third-person (he/she) or first-person (I). Historically, the most commonly used mode in fiction is the third-person omniscient perspective, giving the narrator an overarching point of view.

Narrator The conveyor of the narration, typically in its entirety. The narrator may be an anonymous, non-personal, or stand-alone entity, or appear as a character within the story.

Plot A chain of cause-and-effect relationships, creating a pattern of unified action and behavior.

Prose Language patterns that are consistent with natural grammatical structures and flows of natural speech. Prose is one of the three original verbal arts categories (poetry, drama, prose) of Ancient Greece.

Story A chronicle of events that requires entities or agents to drive the events, otherwise the chronicle is not a story but a sequence of occurrences (not synonymous with narrative or plot).

Verbal art The three verbal arts categories of Ancient Greece were poetry, drama, and prose. Today, verbal art typically refers to creative writing intended for publication, which includes poems, stage plays, screenplays, short stories, and novels.

Novels as Creative Products

Novels have been a topic of modern academic discourse for over four centuries. In this discourse, the generic label of *the novel* typically refers to the product that emerged out of early modern Europe. However, long-form fiction and the literary object that became the modern novel, along with literary criticism and literacy itself, have origins in antiquity. These forms spread across time and across cultures to influence the numerous variations that constitute the novel of the contemporary marketplace. Novels are now written in every major language, the most popular of which are translated for international distribution.

In a recent treatment, *Il Romanzo (The Novel)*—a five-volume collection totaling 4,000 pages published originally in Italian—over 200 voices approached the topic from the latest perspectives regarding history, culture, philosophy, structure, and theme. In the introduction to the two-volume English edition, editor Moretti (2006) proclaimed that the novel was perhaps the first truly global literary product. “The novel is commodity and artwork at once: a major economic investment and an ambitious aesthetic form” (p. ix).

This encyclopedia entry concentrates on novels as historically evolving creative products and what these products reveal about creative writing. Novels can be understood from numerous perspectives, including the ways readers interpret and writers construct. Though multiple views are integral to generating insight, a recurring obstruction is the tendency for normative descriptors such as “the reader,” “the novelist,” and “the writing process.” As the literature from every discipline demonstrates, the only consensus about these singular descriptors is that little consensus exists. There is no reader but readers, no writer but writers, no writing process but processes. Each is complex, varying, and often idiosyncratic, and each influences the eventual creative product, in this case the novel (see Kaufman and Kaufman, 2009, for an overview of research on the psychology of creative writing). External factors such as literacy, culture, and information technologies (to name a few) play critical roles in determining (i) who in history becomes a novelist (and eminently successful), (ii) what writing processes these novelists employ, and (iii) who reads novels and what kinds of reactions these readers have.

In a systems model approach that Csikszentmihalyi (1996) laid out in the opening pages of *Creativity*, “creativity does not happen inside people’s heads, but in an interaction between a person’s thoughts and sociocultural context” (p. 23), where “an idea or product that deserves the label ‘creative’ arises from a synergy of many sources” (p. 1). This model applies to creativity with a capital C, the kind that turns around and influences the culture from which it takes its cues (i.e., eminent and professional artistic creativity that motivates a novelist to write and publish). The three main aspects of this systemic view are: (i) the domain, which consists of the symbolic rules and procedures for the particular creative endeavor; (ii) the individual creator, who works alone or part of a creative group; and (iii) the field, which houses the gatekeepers of the domain. In the parlance of novel writing, the domain is the novel, the individual creator is the novelist, and the field includes the fiction publishing industry and critical readers.

Historical Production

What do novels reveal about creativity in history, about the evolution of creative products, processes, and people, and about domains, fields, and individual creators? In an aesthetic treatment, Lamarque (2003) drew an important distinction between fiction and literature, in that not all fictional work is literary, and not all literary work is fictional. As a creative product and a work of representational art, the novel is as much the result of technological innovation as of cultural drift and diffusion. While characteristics of novels (themes, metaphors, character arcs, etc.) have become as recognizable today as the characteristics of a sculpture or concerto, the particulars are forever evolving and adapting. As Thomas Pavel detailed in *The Lives of the Novel* (2013), long-form narrative fiction is a historical development—a domain-specific type of writing that evolved into what is recognized today as the contemporary novel.

Product Evolution

The novel’s emergence was not haphazard but, like other art forms, dependent on preliminary conditions. The three conditions that needed to occur simultaneously, conditions which remain relevant today, are:

1. public literacy;
2. leisure time and the freedom to read; and
3. widespread reproduction and circulation of written materials.

The first of these two, literacy and freedom, have occurred in multiple societies at different stages in history. For the product now recognized as the modern novel, the third requirement was specific to one occurrence in history: the moveable-type printing press. Today, this third criterion manifests as both print and electronic delivery systems. Despite the secure place of the novel in the contemporary verbal arts, its success is still dependent on the same three conditions. Current societies lacking public literacy, the freedom to read, or the ability to produce or distribute written material also tend to foster comparatively few fiction readers and few if any novelists.

Public Literacy

Evidence indicates that nearly every preliterate society engages in some form of basic narrative practice, in which the human brain works as a kind of meaning-making organ that utilizes narrative cohesion. However, the novel constitutes a higher-level narrative object, the birth of which is specific to the relatively recent emergence of literacy. In an anthropological review, [Goody \(2006\)](#) argued that literacy itself led to long-form narrative construction and coherence, which changed the way that societies and individuals produced and organized meaning. Oral recitation and analogy have been basic forms of storytelling for millennia, but epic narrations (i.e., stories with long metrical runs) require writing. The invention of writing allowed for longer constructions of thought, which in turn placed more importance on time and linear coherence (i.e., a beginning, a middle, and an end), elements often absent from folklore and myth.

As understood from neuroscience, the human brain is not a linear recorder but perceives and stores information in fragments. These fragments get stitched into coherent mental objects such as memories, dreams, speech events, and short narratives. In contrast, long narratives require external organization. In the course of history, the invention of textual mapping (i.e., writing) allowed for larger linguistic constructions, which in turn influenced the way literate people thought. In short, as minds created texts, texts created minds. As literacy became more widespread, narratives became more elaborate.

Subsequently, this arrangement of fragmented thought into linear coherence likely contributes to the criticism of formulaic fiction writing books. Though popular, such books tend to treat language, expression, and writing as a problem of writing (literacy) only. Yet writing is not language, it is an expressive representation of language, which in turn is a manifestation of thought and emotion. Long narrative is the arrangement of this expressive representation (see [Sanford and Emmott, 2012](#), *Mind, Brain, and Narrative*). Specifically, fiction is one type of narrative construction, and the novel is a domain-specific written manifestation of fiction that entails its own affective and embodied characteristics (see [Fairchild, 2019](#), on the psycholinguistic distinctions between different types of writing).

Freedom to Read

The second historical condition for the emergence of the novel was (and remains) the freedom to engage written fiction. Though expressive freedom for thinkers, artists, and writers is necessary for creativity, equally important is an audience's political and economic autonomy. Historically, literacy throughout nearly every society first evolved through the aristocracy, who had the time and freedom to engage advanced language development such as poetry and prose. As civilizations became wealthier and more stable, literacy not only expanded to other tiers of society but became more specialized. Whether Greco-Roman, Persian, Indian, Chinese, Japanese, or Arabic, the heights of each civilization produced urban classes of craftspeople, merchants, traders, and educators, who collectively had enough political and economic freedom (i.e., time away from social obedience and laboring for sustenance) to produce, consume, and trade printed materials. These materials expanded into domain-specific verbal art forms such as published poetry and prose.

In the modern West, what recognizably became the modern novel occurred in step with the European Enlightenment and the Industrial Revolution. These events placed emphasis on intellectual and economic autonomy for the socio-economic commoner, an ideology routinely disseminated through print. As reading consumption increased dramatically during the period and publishing markets expanded, so did the desire for more product variety. In the zeitgeist of a free Western democratic individual, the novel played to the privacy of the reader's own mind and own pace. In short, the freedom to read (and write) a long piece of fiction exemplified the level of one's personal autonomy.

Reproduction

Contributing directly to widespread literacy and audience freedom, the third historical precursor for the emergence of the modern novel was the metal moveable-type printing press. Paper, woodblock printing, and eventually moveable type were all developed in China several centuries prior, which enhanced the production of art and literature across Asia. Due to international trade, both paper and moveable-type technology spread throughout the Arabic world sometime in the 13th century, eventually arriving in Europe soon thereafter.

Although the first book produced by metal moveable type occurred in Korea (c. 1377), it was Europe that saw Johannes Gutenberg's mechanical printing press (c. 1439). The invention not only revolutionized book production, it also fostered mass literacy and the freedom of the individual author and reader. Just as electronic publishing would one day change the way information and products were managed, the printing press bypassed scribes and institutional authorities to give writers more direct access to readers. By the year 1500, European presses had turned out over 20 million copies of print items. A century later, the number had expanded to somewhere between 150 and 200 million. The likes of Niccolò Machiavelli's political treatise *The Prince* (1513) and the entire catalog of William Shakespeare (c. 1589–1613) appeared during this time, as did Miguel de Cervantes's *Don Quixote* (1605), often considered the first modern novel of international recognition.

Modern Novel Writing

What do novels reveal about creative writing processes? The quest to pin down a definitive writing process has been the subject of prescriptive writing advice for decades. However, in a review of evidence on creative writing processes, [Lubart's \(2009\)](#) general conclusion was that creative writing is a kind of problem-solving process so idiosyncratic that likely no single process could exist.

The problem goes beyond that of merely defining the specifics of a particular domain. In the domain of novel writing, processes can vary author by author and often novel by novel, with an individual author sometimes producing one title alone at night in the dark and then producing the next title by day in a crowded coffee house.

Rather than trying to isolate a recipe that aspiring authors should or should not employ, the creativity concept of flow, or optimal experience (Csikszentmihalyi, 1996), presents a promising alternative for the understanding and development of fiction writing. In a review of qualitative research on flow and the art of fiction, Perry (2005) addressed the mental states, habits, and environmental conditions in which numerous successful authors find themselves. Exploiting these states and conditions liberates each individual author from prescription, which allows them to conduct writing in whatever personalized manner is effective.

The considerations around flow match the advice that Burroway (2019) presented in *Writing Fiction*, one of the most commonly used practical fiction guides of the past 30 years. In addition to outlining the major components (objects of craft) for aspiring and practicing novelists, Burroway asked writers to consider themselves as central to individualized writing processes (methods of craft). In terms of application, when trying to enter into something like a state of optimal writing, writers and writing processes should be treated as inseparable. Burroway organized her advice around nine topics:

1. The writing process: whatever works.
2. Seeing is believing: detail, imagery of emotion, voice, rhythm.
3. Direct characterization: dialogue, appearance, action, thought.
4. Indirect characterization: interpretation, credibility, purpose, complexity, change.
5. Setting: atmosphere, harmony and conflict, symbolism.
6. Plot and structure: conflict-crisis-resolution (the story arc).
7. Point of view: who speaks to whom, and in what form and at what distance?
8. Comparison: metaphor, simile, symbols, the object correlate of the conflict.
9. The rewriting process: what is working and what is not?

The Reality of Drafting

Fiction writing is a domain-specific enterprise, where writing reasonably well in one domain is no guarantee, nor indicator, of being able to draft a novel. Fig. 1 shows the pyramidal stages in the practical development of a novel today, which ties into the creativity literature (Csikszentmihalyi, 1996; Simonton, 1994) on eminence and the great investment of time needed to write successfully. Most aspiring novelists never get past the first stages, of having some initial ideas, completing a few pages, and maybe completing a draft. If a writer manages to arrive at a working manuscript, an industry consensus is that fewer than 1% of these manuscripts are ready for publication, leaving the writer with one of three choices: do more redrafting, start a new story, or quit writing. If a manuscript does manage to become a published novel, less than 10% of these will achieve critical or commercial success, and less than 1% of these successful titles will become bestsellers.

Emotional Crafting

In *The Emotional Craft of Fiction*, prominent literary agent Donald Maass (2016) stressed that a successful novel is, among many things, a successful emotional rendering, a point supported in various psychological, philosophical, and narrative investigations of fiction (e.g., Carr, 2014; Hogan, 2011). Sanford and Emmott (2012) reviewed research suggesting that fiction writing is also a textual representation of embodied experience, a conclusion supported by a quantitative study (Fairchild, 2019) indicating that prose fiction is perhaps the most embodied form of writing. Writers can deliberate over the proper ways of crafting a text and are even permitted a certain number of fiction writing blunders, as long as the story hits the reader in the emotional gut. Without this affective resonance, which is partly an embodied resonance, a novel loses a reader's interest.

As Carr (2014) discussed in a review of research on the aesthetics of literary fiction, readers—in their complex plurality—are an integral social and psychological component in determining the aesthetics (desirability and creativeness) of a published novel.

Figure 1 Stages of a novel.

Although evidence shows that fiction readers often learn something new about themselves and the world around them, they also seek (consume) stories to satisfy preexisting beliefs, feelings, and worldviews (Carr, 2014; Maass, 2016). The situation generates a precarious line that authors must walk, between telling challenging stories and placating the human desire for familiarity and comfort.

Fiction Narration

“The house of fiction has many windows but only two or three doors,” wrote literary critic and scholar James Wood (2008) on the opening page of *How Fiction Works*. The two doors refer specifically to third-person (he/she) and first-person (I) narration, and nearly every novel ever written is in one of these two voices. Third-person is typically written from the omniscient view, whereas first-person is sometimes referred to as the unreliable voice, because the narrators tend to know less about themselves than the readers eventually do. In practice, neither type of narrator is entirely reliable nor unreliable. Third-person can range from narratively neutral to narratively biased and sometimes heavy handed. Likewise, first-person narrators can be intimately reliable, such as Charlotte Brontë’s *Jane Eyre* (1847) (a work that helped revolutionize individual character consciousness in modern fiction). First-person can also be obsessively unreliable, such as the anonymous narrator of Dostoevsky’s *Notes from Underground* (1864) (a work that demonstrated the limits of character self-awareness for generations of future fiction writers).

Both Brontë and Dostoevsky revealed important aesthetic and psychological aspects of a narrative text, and what separates something like memoir, journal writing, or the personal essay from a novel. The primary distinction concerns the natures of nonfiction and fiction, of representing something that claims a basis in reality as opposed to using representational reality as a means to convey a theme, message, or emotion. Whereas the writer of a memoir, for instance, is typically expressing a personal perspective directly, the author of a novel will construct a narrator, and the narrator is the revealer of a story that automatically limits information about the writer. One purpose is to craft a kind of theatrical mask, or authorial character, to help take focus off the writer (i.e., biases off people, beliefs, etc.) and direct it toward the writing (i.e., focus on the messages and themes within the text).

The uses of masking and implication are as old as storytelling itself, and each is implicit in human behavior. In an in-depth introduction to narrative psychology, Laszló (2008) discussed how the implied voice occurs naturally, as a complex identity among the structures, psychologies, and historical truths of how people routinely and unconsciously construct their worlds and selves. Theatrical masking differs from ordinary masking in that someone like a fiction writer, both intentionally and unconsciously, will employ implied voicing to buttress the dramatic and thematic agendas. This engagement must not be confused with deception, which is an evasion of truthful understanding.

Although fiction authors can and often do borrow fragments of true life occurrences, they nonetheless invent characters and images throughout the rendering of the text. In the process, fiction authors make exponentially more conscious word and grammar choices, sometimes taking liberties with the accepted meanings and rules of linguistic engagement. Rather than trying to deceive the reader in this way, the author is typically intending to convey a more specific story or implicit emotional theme, one that is perhaps difficult to develop through conventional language alone. In *Deeper than Reason*, a treatise on emotion in art and literature, Rob-inson (2005) insisted that a novel should be understood in relation to its implied author, which serves as a buffer between writer, text, and reader. Formal devices, such as voicing, verb tense, and metaphor help build this buffered space, through which emotional, unsettling, and even disgusting subject matter can be engaged from a safe distance.

Domain Changes

What do novels reveal about a core creativity topic like domains and the conventions within each domain? Major bestsellers throughout history have ranged anywhere from 650,000-word epics like Victor Hugo’s *Les Misérables* (1862) to numerous 100-page novellas that include Charles Dickens’s *A Christmas Carol* (1843) and George Orwell’s *Animal Farm* (1945). The novella in particular, a literary form that began during the Italian Renaissance, enjoyed a dominant run in English-language markets in the latter half of the 19th century and early part of the 20th. The compact length (approximately 17,500 to 40,000 words) appealed to an emerging mass audience and an industry needing to sell books in quantity. In the United States, the novella was the premise for the market paperback, a cost-effective commercial product that could generate substantial sales from titles like Edgar Rice Burroughs’s *Tarzan of the Apes* (1912). For full novels (over 40,000 words) and works of literary fiction during this same era, word counts tended to be relatively low but there was considerable variation overall.

In the contemporary marketplace, most English-language novels fall within a range of 75,000 to 100,000 words, or roughly 300 to 400 manuscript pages. For unknown or first-time authors, the page-count heuristic is closer to 250 to 400 pages (62.5k to 100k words), as market research indicates that typically anything shorter and usually anything longer ends in lower sales (readers want something for their money yet tend to avoid lengthy novels by unknown writers). Accordingly, agents and editors generally reject new authors whose manuscripts fall outside this window. In comparison, established authors, for better or worse, often get away with a pattern of inflation, in which manuscript lengths increase as an author becomes more popular. Two authors known for inflated word counts are Stephen King and J. K. Rowling, but only after each broke into the fiction market with first titles that were the shortest of their respective careers:

- Stephen King,

first four novels and apx. word counts (in thousands):

<i>Carrie</i> (1974)	61k
<i>Salem's Lot</i> (1975)	152k
<i>The Shining</i> (1977)	166k
<i>The Stand</i> (1978)	471k

- Stephen King (writing as Richard Bachman),

first three novels:

<i>Rage</i> (1977)	54k
<i>The Long Walk</i> (1979)	85k
<i>Roadwork</i> (1981)	90k

- J. K. Rowling,

the seven Harry Potter novels:

<i>The Philosopher's Stone</i> (1997)	77k
<i>The Chamber of Secrets</i> (1998)	85k
<i>The Prisoner of Azkaban</i> (1999)	107k
<i>The Goblet of Fire</i> (2000)	191k
<i>The Order of the Phoenix</i> (2003)	257k
<i>The Half-Blood Prince</i> (2005)	169k
<i>The Deathly Hallows</i> (2007)	198k

Authors of Novels

What do novels reveal about creativity and authors? If for no other reason, a historical understanding of a novel (or any creative product) is important because time is important to creative judgment: the time of the novel's publication, the reputation of the novelist at different times in history, and the changing sentiment over time in the domain's field (gatekeepers, culture, marketplace). One example of this systemic confluence of domain, author, and field concerns the novelist and poet Mary Shelley (1797–1851). Only 18 years old when she completed her first draft of *Frankenstein* (1818), Shelley initially published the novel anonymously to deal with the age and gender biases of her day. A review from the prestigious *Quarterly Review* also captured the critical rejection typical for the novel at the time of its release:

Our taste and our judgment alike revolt at this kind of writing, and the greater the ability with which it may be executed the worse it is—it inculcates no lesson of conduct, manners, or morality; it cannot mend, and will not even amuse its readers, unless their tastes have been deplorably vitiated ([Croker, 1818](#), p. 385).

Although unfavorable among many critics, *Frankenstein* struck a chord with audiences and would eventually become the most important foundational piece of both modern horror and science fiction. Shelley today is considered one of the most influential female authors of the 19th century, yet this is a relatively recent phenomenon. As late as the 1980s, Mary was largely remembered for being the wife of Percy Shelley, whose poetry and reputation she helped elevate to eminent status after his premature death. Not until more female scholars appeared in academia did new collections of Mary's work emerge, along with the first full-length scholarly biography, which resurrected her writings and helped build her contemporary reputation.

Female Authors

Shelley's story, of creative talent, critical dismissal, and constant financial struggle during her lifetime, is not unusual for creative writers in general. For a widow like Shelley, the additional challenge was raising her only surviving child—a son who fortunately ensured that his mother did not die destitute as many writers had. While history contains similar stories of women in a struggle to catch up to male counterparts on most fronts of creativity, the presence of female fiction authors was so apparent by the middle of

the 19th century that British writer and critic Margaret Oliphant at the time declared an “age of women novelists” (cited in Connor, 2018, p. 139). Still today, in the history of English-language authors, the most enduring female names are from the 19th century (e.g., Jane Austen, Kate Chopin, the Brontë sisters) or from the first decades of the 20th (e.g., Willa Cather, Edith Wharton, Virginia Woolf).

In brief, women have been a major force in the development of the novel, and not just in the West. In Japan, for instance, Murasaki Shikibu drafted her 1,100 installment pages that became *The Tale of Genji* (c. 1002–1008), sometimes considered the first real novel in world history written in vernacular prose. Beyond Murasaki, however, female names remain largely absent from the canon of Japanese literature, which studies in Japan and the West (e.g., Simonton, 1992) attributed to the patriarchal reinforcement of Japanese civilization and not to the lack of creative women. Written Japanese itself is conducted by using three scripts: a formal Chinese pictography (*kanji*) and two phonetic scripts. Women, who were excluded from formal language learning (*kanji*), first mastered the more vernacular and colloquial forms of phonetic writing, as Murasaki did. One result was a prose form that laid the foundations for centuries of Japanese fiction by both female and male authors.

In Western societies, the increase in the number of female authors occurred in step with the rise of female literacy. Literacy was deemed useful for increasing a young lady’s prospects for marriage. However, the more that young women read, the larger appetite they developed for fiction, for wanting a single life, and for pursuing writing careers themselves. This desire for independence fueled a recurring backlash toward women authors, their publications, and their readers, all deemed romantic, emotional, and misguided by fancy and fantasy. *Don Quixote* itself was Cervantes’s rebuttal to chivalry, enchantment, and romance, a rebuttal that critics later transformed into the realist-idealist sensibility that became the platform for modern fiction.

The dominance of male literary influence, as seen throughout most of the 20th century, was partly a phenomenon of Western modernism itself. The birth of modernism came at the expense of romanticism, when subjective language was replaced by a pointed psychology (i.e., a mislabeled feminine emotionality replaced by a masculine seriousness). The timing occurred with the emergence of mass education and literacy, commercial mass market publishing, official literary prizes, and academic literary entrenchment. The full arrival of the American novelist occurred during this time, led by such names as William Faulkner, F. Scott Fitzgerald, Ernest Hemingway, and John Steinbeck. The environment helped ensure that the modern masculine voice would be the voice of the 20th century novel. From its inception in 1901 through the year 1990, the Nobel Prize in literature was awarded 85 times, yet only six times to women (in 1909, 1926, 1928, 1938, 1945, and 1966). Women fared better with the Pulitzer Prize for fiction, receiving 26 of the 89 awards (29%) as of 1990. Not until the end of the 20th century would Western female authors reestablish their strong creative influence over fiction writing and the market.

The Field of Novels

What do novels reveal about creative conventions, about the function and practices of the novel’s field including the publishing industry?

Genre

In the verbal arts, the three genres from Ancient Greece are poetry, drama, and prose. In the business of novel writing today, the two most fundamental types are literary fiction and commercial (genre) fiction. Commercial fiction is what the descriptor implies: novels that generate profit for publishers, as fiction consumers tend to select titles based on (i) loyalty to a particular author and (ii) interest in a particular genre. In literary fiction, the product is the prose itself, often focusing on the inner lives of the characters attempting to navigate traditionally, commonly, or universally held themes such as love and death. Such novels take most of the prestigious literary awards, and many can become bestsellers, though the majority tend to lose money and are thus typically handled by publishers dedicated to this type of fiction. In practice, with the recent industry emphasis on distribution and marketing, nearly every novel is now categorized by one or more genres. In query letters to most potential agents or editors, unknown authors (literary and commercial) must provide genre identification for their pitched manuscripts if they hope to be considered at all.

Given the emphasis on genre, the number of fiction genres has expanded over time along with the variety of subgenres. An example is science fiction (SF), which developed subgenres that include hard SF (technologically driven), soft SF (character driven), and space opera (galactic warfare and melodrama). Genres also overlap with one another. For instance, fantasy is a genre on its own, but fantasy also exists as a subgenre within nearly every major genre (e.g., fantasy western). Seven of the major genres and their common subgenres include:

- Fantasy: fairytale, magic realism, sword & sorcery, urban;
- Horror: aliens, hauntings, mind control, supernatural;
- Mystery/Crime: cozy, detective, hardboiled, police procedural;
- Romance: contemporary, gothic, historical, paranormal;
- Science Fiction: alternate history, feminist, cyberpunk, steampunk;
- Thriller: espionage, legal, medical, military, political, techno; and
- Western: cattle drives, lawmen, lost mines, railroads.

The genre market extends across cultures as well, including the best-selling genre of all time: romance. For the year 2008, *The Wall Street Journal* reported that nearly 75 million people globally read English-language romance novels, and the leading American romance publisher, Harlequin, sold half of its product internationally. The number of romance subgenres is currently in the dozens, with contemporary romance generating half of the entire genre's sales. There is even a lucrative graphic novel subgenre in Japan known as boy's love (male homosexual romance), which is created and read almost exclusively by women.

Agent Perspective

Historically, the middleperson who helped transition a fiction author's manuscript into a published novel was the editor. Though the position of editor is still paramount in the publishing industry, many fiction editors do little editing and have become acquisition agents for publishers: private, profit-driven businesses that invest little interest in fiction authors who lack commercial track records. The result has led to a growth in the number of literary agents. Although many experienced novelists have learned to deal with publishers directly, agents have become a common bridge between art and commerce, an area in which most writers are the least experienced and the least comfortable.

Unlike a writing teacher or a fellow writer, who might devote considerable time and sensitivity to an aspiring writer's work (or unlike an academic who spends considerable effort on abstracting information on creative writing), literary agents operate in much simpler terms. Is a manuscript any good (i.e., is it publishable)? Will anyone buy it? More than 99% of the time the answer to both questions is no, and most queries submitted to agents are rejected outright. To the inexperienced author, this can seem like a hasty judgment of one's hard labor (contributing to the growth of self-publishing despite its poor showing for writers). In practice, the agent is often the best and sometimes only ally that a novelist will have. Reputable agents are successful only if their clients are successful, securing publishing deals in an industry saturated with product. Unlike nonfiction publishing, where a book proposal leads to a commissioned deal, a novel must first be completed and dealt to a publisher much like a finished painting is brokered to an art dealer. The result is an established industry that favors the commodity of known authors. For a new author, the best option is often a less-established agent, one willing to take risks on an unknown.

The Continuing Evolution

This entry attempted to address novels and creativity in relation to the aspects of domain, individual creator, and field. Historical and contemporary developments inform the understanding of creative products like a novel (and a creative person like a novelist) as emerging from a synergy of many forces rather than isolated occurrences.

One conclusion is that novels, novelists, and their writing processes manifest in the plural. In year 1953, James Baldwin published his semi-autobiographical first novel, *Go Tell It on the Mountain*, a breakout title for African-American writers and still listed on most top-100 lists for best English-language novels. In 1958, Nigerian author Chinua Achebe published *Things Fall Apart*, a breakout title for African writers and still the most widely read African novel globally. In 1968, the Nobel Prize for literature was awarded to Japanese novelist Yasunari Kawabata, the first non-Caucasian in the Prize's history, for a body of work that explored the boundaries between human beauty and frailty, between deep introspection and illicit behavior. In 1989, Laura Esquivel published *Like Water for Chocolate*, a number one bestseller in both her native Mexico and in the United States. What each of these novels had in common were their differences: different writing processes by each author, different uses of voicing and character perspective within the texts, and different publishing avenues toward different readers.

Baldwin, Achebe, Kawabata, and Esquivel are but four names that represent the diversity and international range of the novel today. Authors from different cultures, in different languages, have crossed old thresholds to take the novel in new directions while following domain conventions such as narrative, theme, plot, story, character, and human emotion, and field conventions such as genre, publishing trends, and the plurality of reader audiences. In conclusion, the novel is an established, creative form, but novels and novelists are not static and continue to evolve.

Glossary

Domain An area of knowledge or expertise.

Novelty A kind of variability involving responses that are new and (1) appropriate/useful, (2) generative, or (3) influential.

Paired Constraints Tools for increasing novelty. Constraints come in pairs. One of each pair precludes a reliable, predictable response while the other promotes an atypical, unexpected one.

Problem Space How a problem is represented by a solver. The space has three parts: an initial state, a goal state, and a search space in which a solution path is constructed.

Solution-by-Substitution Step by step construction of the solution path.

Variability A measure of how differently something is done. Moderately high variability is associated with usefulness; higher variability, with influence.

NOVELTY is necessary but not sufficient for a response to be considered creative. Nonetheless, given that the criteria for sufficiency (usefulness, influence, etc.) are many and shifting, novelty may be the optimal object for manipulation and measurement. This entry considers how paired constraints preclude low variability, high probability responses and promote novel ones.

Novelty, Variability Levels, and Learning

Variability can be conceived as a continuum with minimal and maximal degrees of difference in how something is done. Fig. 1 presents one version of such a scale. Responses closer to the minimal end of the continuum are predictable because they tend to be performed in remarkably similar ways. They increase variability from stereotyped (invariant) to reliable (habitual) to expert (variation between “successful” solutions).

Responses closer to the maximal end are less predictable because they are, by definition, quite different. Novelty is in this range because new responses appear after more likely ones have been exhausted. The kinds of novelty include responding that is new and appropriate or innovative or influential.

Appropriate/useful is the most common kind of novelty: it simply solves the problem at hand. In generative novelty, the solution propels its own development. Influential novelty expands domains. Here, at the highest level, the novelty changes the way others look at, think about, and, importantly, solve problems in a particular domain.

This article is an update of P.D. Stokes, Novelty, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 186–191.

Figure 1 Variability continuum.

Learned Variability Levels

Learned or habitual variability levels (how differently one usually performs or applies a skill) are domain-specific and learned/acquired early in skill acquisition. High levels ensue when training requires and rewards doing something in multiple ways. This kind of regime can be thought of as difficult-but-doable; accelerated training is another, in which rapid acquisition of different skill components precludes repetition and promotes variation.

Novelty, Problem-Solving, and Constraints

A counter-intuitive (i.e., counter to common usage) strategy for increasing novelty involves imposing constraints, plural and paired. Since the pairing is a convention from problem-solving, our discussion starts with problem spaces.

Problem Spaces

A problem space is how an objective problem is represented (subjectively) by a potential solver. Experts and novices differ considerably in this: the expert's representation is both more elaborate and more efficient. In both cases, however, the parts of the space are the same. There are three:

- The initial state, which represents the current situations.
- The goal state, which represents the desired, changed situation.
- The search space, in which a solution path is constructed to transform the initial into the goal state.

Paired Constraints

In problem solving, constraints come in pairs that guide the construction of the solution path by precluding elements of the initial state and promoting substitutes. The path is the series of substitutions that produce the promote column. As shown in [Table 1](#), there are four constraint categories.

Goal constraints preclude an existing solution (the initial state) and promote a novel one (the goal state). Source constraints are elements that you work against (preclude) or with (promote). Subject constraints involve content or motif; task constraints, materials and how they are used. Constraints cascade when one pairing suggests or requires another. The greater the cascade, the greater the novelty.

Table 1 Constraint categories

Category	Pairings
Goal	Preclude an existing style/solution → Promote a novel style/solution
Source	Preclude (work against) specific elements → Promote (work with) others
Subject	Preclude particular themes/motifs → Promote others (often opposites)
Task	Preclude traditional materials and Manipulations → Promote alternative materials and Applications

Table 2 Constraints for original tile designs

Category	Pairings
Goal	Preclude “intruder’s” designs → Promote substitutes
Task	Preclude symmetry → Promote asymmetry
	Preclude multiple colors → Promote limited colors (red/black)
	Preclude staying inside grid → Promote extensions outside the grid

Novelty Problems

There are two kinds of novelty problems. One, the Basic Novelty Problem is initiated by an outsider (typically a researcher studying conditions that facilitate novelty or variability) who presents the problem to someone else (usually a novice) for solution. Their solutions belong in the novel/appropriate and category. The other, the Advanced Novelty Problem is initiated by an expert solver. Solutions here may become generative or influential.

Basic Novelty Problems

Increasing novelty. In these problems, those reliable, habitual responses found at the low end of the variability continuum are *precluded*. In their places, newly appropriate or useful responses are *promoted*. Examples are sorted by kind of task.

Drawing. The first two studies in this section involved children. In the first, a promised reward for completing a drawing task only increased originality when children were given *explicit* instructions that the drawing be unusual, or when they had just been rewarded in the same classroom for coming up with unusual rather than ordinary uses for objects. In the latter case, the *context* seems to have cued *transfer*. This is basic operant conditioning: in this context → this response leads to → this consequence: Here, in this classroom → *precluding* usual and *promoting* unusual responses leads to → reward.

In the second, where the task was making drawings that incorporated pre-printed circles (16 on a single sheet of paper), originality (operationalized as complexity) depended on the drawing examples presented. One group of children were shown a single smiley face; the other saw both a goldfish bowl (with parts protruding from the top and bottom of the bowl) and a bicycle (using two adjacent circles). Unsurprisingly, originality was higher in the dual example group. In this case, the examples served as an *implicit* constraints: either *preclude* simple, stay inside the circle → *promote* complicated, draw outside the circle, combine circles, or vice versa.

The next two studies were done with college students. The very early one *explicitly* instructed students to make abstract designs with a black pen: first, three designs different from each other, then different from the first three, then different from designs made by an “intruder” (the intruder was the experimenter), finally, just 3 designs. The very interesting result was that the most original designs appeared in the final set, when the designs were noticeably different from the “intruder’s” drawings. This result was recently replicated (but not yet reported) using with students using magic markers to draw tile designs on 4 by 4 grids. Again, the most original designs appeared in response to the “intruder’s” designs. It seems that *precluding* elements of your own style is not as simple, or perhaps as obvious, as *precluding* elements of someone else’s.¹

Table 2 represents a possible problem space for the final set of tile designs. The preclude column lists elements of the “intruder’s” designs; the promote column, the student’s substitutions.

Inventions. In one set of studies, researchers manipulated choice of inventive categories (subject constraints) and parts (task constraints). The *explicit* goal was to produce novel, useful objects, by combining the parts. The researchers reasoned that greater choice would promote conventional thinking; thus, they predicted that limiting choice would *preclude* habitual/conventional responses and *promote* novel ones. Their prediction was correct. Compared to conditions where students chose either category (e.g., furniture or toys) or parts for combination (e.g. wheels, handles), the highest originality ratings were given when both category and parts were randomly specified rather than selected. In another, related study the *explicit* goal was designing a toy for a child (age 5–11). Again, novelty ratings were higher when parts were restricted.

Movement. In a famous early study, porpoises were rewarded for swimming and leaping in ways that were outside the species’ normal repertoire. Novelty was defined *across* sessions: to earn a fish, a response had to differ from all responses in all sessions. So, *preclude* all previous topographies, *promote* novel ones. Did the porpoises notice out what the fish were for? Yes. As training proceeded, new topographies appeared closer to, and even, at the start of a session.

More recent work in sports psychology manipulates practice task constraints to increase “functional novelty,” i.e., new, efficient movements based on discovery/exploratory practice. What gets explored are “affordances,” properties of objects that suggest ways to use the objects. For example, a pen “affords” writing. It could also “afford” stabbing or scratching. manipulations shown to increase exploration (and facilitate discovery of novel efficient movements) are changing task constraints and suppressing habitual responses. In both cases, current conditions and responses are *precluded* in order to *promote* exploration and, as a result, functional novelty.

¹This (precluding elements of another’s style) is how shifts in art paradigms occur. Pop Art, for example, precluded specific elements of Abstract Expressionism and promoted direct opposites.

Increasing Variability. In these problems, the goal is *precluding* lower and *promoting* higher variability per se. Most familiar to creativity researchers are Divergent Thinking problems, solutions to which are measured as number of different responses (fluency), number of different response categories (flexibility), and number of unusual responses (originality). Less familiar are procedures that specify lags or manipulate task difficulty.

Lags. A lag is the number of prior responses from which a current response must differ. For example, a lag of three means that reward only follows a response (or series of responses) that differs from three prior ones. Imagine three-response sequences made on right or left pointing arrow keys: the sequence RRR would be rewarded if it occurred after the sequences RRL, LLL, and LRL, but not if any triad was repeated (e.g., RRL, RRL, LRL). Lags clearly preclude repetition and promote variation. They have been shown to increase response variability in pigeons, grade school and college students. Pigeons have met lags up to 50; college students to 25; fifth graders to 10.

Another procedure is known as frequency dependent selection. Here, less probable or less frequent responses are momentarily selected for reward. For example, with the same left-right key press pair, as R increases in frequency, reward decreases for R and increases for L. Depending on the relative probabilities specified by the reinforcement schedule, some stable (and more or less variable) alternation pattern will earn maximal reward.

Task Difficulty. Implicit variability criteria are embedded in all tasks; they differ depending on whether the task is easy or difficult, simple or complicated. An easy or simple task requires little variability: few things need be tried to master it, few to maintain it. Difficult or complicated tasks require higher variability: many things are necessary for mastery and maintenance. Importantly, whether high or low variability levels are temporary or habitual depends on when a particular type problem is introduced. As mentioned earlier, habitual variability levels – preferred performance ranges – are acquired early in skill acquisition. If easy/simple tasks are encountered then, the levels will be lower than if training involves difficult/complicated tasks.

Computer maze games have been used to *preclude* or *promote* high or low variability levels. For example, two groups of college students played different versions of a game with easier/simpler or more difficult/complicated set of constraints. The easy set required exiting the maze at specific locations; the difficult one, exiting at the same locations by paths that differed from some number of prior paths (in other words, lags). For example, exit from locations C or D by a path different from 2 immediately prior paths. As the number of locations decreased (from 3 to 1), the lags increased (from 0 to 5). The more difficult training task (combined locations and lags) generated higher variability both when the training conditions were in effect, sustained it after they were relaxed (i.e., when all paths to all locations earned points), and facilitated *transfer* to a novel task (alternating exits on the maze). The transfer effect, suggest multiple researchers, is due to high variability requirements sensitizing the learner to changes in condition.

Domain Specific Novelty Problems

In Domain-Specific Novelty Problems, the initial state is usually an existing, accepted style or solution type. The initial and goal states together are the preclude-promote pairs of the goal constraint. This section summarizes constraints in two domains – architecture and theatre – that attained the highest level of variability criteria, influence.

Architecture

Here we focus on one type of architecture (domestic) and one architect (Frank Lloyd Wright). The open, interconnected spaces of Wright's Prairie (palatial) and Usonian (practical) houses were highly *influential*, prototypes for single-level ranch house, satellite spaces, and great rooms. As indicated in Table 3, his goal precluded the straight-sided box with its small, separate rooms (initial state), and promoted in its place, a radically new architectural style that he labeled "organic" (goal state). For Wright, "organic" was synonymous with "continuity." Continuity involved three relationships: between interior and exterior spaces; between interior spaces; between surface and decoration. To accomplish this, he sourced horizontal elements (overhanging roofs, transoms, open spaces separated by sliding screens) from the traditional Japanese dwelling; balconies and verandas from the South; hearths and porches from the Midwest; simplified, stylized, and importantly – unbroken – surface decoration from his mentor, Louis Sullivan.

The site was critical in that the house conformed to, was an extension of, its topography. Most Wright sites were flat, which accounts for the horizontality of the Prairie and Usonian houses. The most famous exception is Falling Water, with cantilevers that overhang and mimic its waterfall. Critical to realizing a continuous, open plan was the modern of materials at the time: reinforced concrete solved the problem of support. Multiple interior walls (which necessitated small, box-like rooms) were supplanted

Table 3 Constraints for Frank Lloyd Wright

Category Pairings		
Goal	Preclude the "box"	→ Promote the "organic" (continuity)
Task	Preclude interior-exterior separation	→ Promote site-specific elements (cantilevers, strip windows, overhanging roofs, terraces)
	Preclude interior separation	→ Promote open, interconnected plans (piers, columns, screen walls)
	Preclude surface-structure separation	→ Promote structure-specific elements (decoration follows form)

Table 4 Problem space for Commedia

Category	Pairings
Goal	Preclude Elizabethan theatre → Promote formal exaggeration of reality
Subject	Preclude changing subject → Promote single subject (survival)
Task	Preclude changing characters → Promote prepared parts
	Preclude realistic → Promote caricatured (types, masks, etc.)
	Preclude written, memorized → Promote improvised
	Preclude acts → Promote scenario

by fewer, lighter supports (piers, columns) beyond which Wright's organic, continuous plans could expand. Bridging the final separation (between surface and structure), decoration was derived from form: linear, geometric elements and patterns iterated the shapes of their supports. The house, in Wright's plans, was no longer divided.

Theatre

The epitome of influence in comedy is *Commedia Dell'Arte*. What did Commedia work against? Basically Shakespeare, the most famous of Elizabethan dramatists. The *preclude* column in [Table 4](#) lists elements found in Shakespeare's comedies and tragedies. The *promote* column presents the substitutions, the solution path that realized *Commedia's* sub-goal, the formal exaggeration of reality.

Commedia's modular structure (prepared parts/scenario) is formal, the exaggeration in the caricatured types with their associated masks, *maschera* and *lazzi*,² and the reality in the singular subject (survival, endlessly threatened by the problem that propels the play). The problem places the types in a scenario to which each reacts spontaneously because she/he is always prepared ("in character" and often, in a troupe, in the same character). The problem proliferates, the scenario shifts, "solutions" produce new problems, until (at last) order is restored, and survival (temporarily) assured.

Influence? The earliest company appeared in Padua in 1545. There are current companies and multiple offspring, including sitcom, soap opera, stand up, and of course, improv. What keeps *Commedia* and its progeny popular? Something similar to sports. "The game is always the same, rules, players, props, and playing field are givens. This makes exceptional play not only possible but noticeable. Appreciation is maximal because the structure is known; anticipation is maximal because the outcome isn't" (Stokes, 2016).

What are *Lucy*, *Jerry* (Seinfeld), and (Unbreakable) *Kimmy Schmidt* if not children of *commedia*?

Concluding Questions and One Suggestion

The Questions

There are multiple questions about novelty.

- One involves criteria: is something not-so-new, sort-of-new, truly new?
- Two relates to the truly new: how easily, how soon, will it be accepted, adopted, adapted?
- Three is the most basic and the most difficult: How do you do something new? The answer, developed in this chapter, is you use constraints to *preclude* a current style/solution and *promote* a substitute.
- Four follows from three: where do the substitutions come from? The answer is something new (to this chapter): the *tool box* inside your head, the one you can't think outside of.

And one question about the tool box: what's inside it?

Two things: Basics and borrowings.

Basics are your expertise – things you know and things you can do. This is where training for novelty comes in. Acquisition of basics should begin early and be accelerated so that students not only acquire repertoires replete with elements for recombination and restructuring, but also the high habitual variability levels necessary to do so.

Borrowings are things that make your tool box bigger. They come from other domains. (Paired constraints are a strategy you can borrow from problem-solving). They are things noticed when needed. (Think of Pasteur and chance). Borrowings make your tool box bigger.

The Suggestion

The suggestion should be obvious. *Make your tool box bigger*. Absorb, acquire, copy, collaborate, investigate, and do take chances. Since you can't think outside the tool box, the novelty of your solutions depends entirely on its contents.

²The mask is a half-mask, leaving the lower lip and chin uncovered. This precludes using facial expressions to convey emotions, and promotes the *maschera* (gestures, postures, gaits, and attitudes) associated with each mask. The *lazzi* are prepared comedic bits linked to specific masks.

Introduction

Opera is the pinnacle of the performing arts, incorporating singing, acting, orchestral music, and sometimes dance. For good reason, composer Richard Wagner called opera *Gesamtkunstwerk*, or “the complete work of art.” An art form more than 400 years old, opera is a profusion of laments, patriotic choruses, intricate quartets, triumphal marches, flirtations, jealousy, and love. In the words of opera and film director Franco Zeffirelli, “Opera is a planet where the muses work together, join hands and celebrate all the arts.”

Creativity exists among the eminent composers and singers, and also among less visible participants. Dozens of talented artisans contribute to every production: set designers, costumers, and lighting designers, exhibiting what has been called “everyday creativity.” Administrators strive to make appealing repertoire choices and effective marketing campaigns to retain established audiences and entice new ones.

After a brief history, the following sections describe the creative contributions of composers, librettists, conductors, stage directors, and others, asking, “*In what way* is each opera participant creative?”

History

Opera as we know it dates from 1597, as an elite musical form for royalty and other privileged classes, setting to music the ancient tales of gods, goddesses, and kings. Musical styles evolved, from baroque to bel canto, romantic, verismo, modern, and post-modern. The focus on gods and royalty faded, comedies about clever barbers, country romances, and sleepwalkers won admirers, and by 1853 Verdi’s *La Traviata* sympathetically portrayed a high-class courtesan’s sad ending. The even bigger departure in Bizet’s 1875 *Carmen* and other verismo operas at the end of the century depicted life and death among peasants, dock workers, soldiers, and rebellious independent women.

Accordingly, the level of cultural knowledge required of a patron changed over time. When operas were about the doings of gods and kings, one had to be familiar with the classics to gain the most from an opera. *Verismo* operas of the late 19th century brought stand-alone stories and dialogue with minimal reference to the common cultural heritage. Knowing the language in which the opera was set once made a greater difference than it does now, when glossy programs offer plot synopses and supertitles translate the dialog in real time.

Etiquette and decorum for audiences also changed. Dressing up for the occasion may once have been common, but today expectations have loosened so that attire varies from formal to blue jeans – though those wearing the latter are sometimes the most knowledgeable patrons in the house. Rituals such as shouting “bravi” correctly in Italian and waiting by the stage door to greet favorite performers persist. Throwing bouquets during curtain calls has dwindled, perhaps from distaste for the spectacle of singers awkwardly dodging flowery missiles.

In the 20th century, a movement variously called atonal, twelve-tone, and Serialism rejected traditional music theory and harmonies, favoring dissonance, irregular rhythms, and jarring sounds. It became fashionable among certain people, including critics who (perhaps dreading to resemble unlucky earlier critics who panned *Rigoletto*, *La Bohème*, and other masterpieces), praised them (see [Reviewers](#)).

With few exceptions, these operas were not liked by American audiences. Finally, general directors realized that most twentieth-century operas were repelling their patrons and began to practice risk aversion by not scheduling them. Matthew Shilvock, General Director of San Francisco Opera, observed a regional difference between opera cultures, noting that “There’s still a very active and respected tradition of more atonal work, and more contemporary, non-lyrical works can sell out theaters in Europe” (personal communication, March 6, 2019). However, David Gockley, one of America’s great impresarios, concluded: “After three centuries of tonal consonance in music, the atonal revolution of the early 20th Century, brought on by Schoenberg and his Second Viennese School, blew the musical world apart Finally, in the 1970s Philip Glass brought his signature minimalism to the Opera ... It has helped to remove the stranglehold that Serialism had exerted on the art form” (personal communication, January 6, 2019). Newer operas are more likely to be approachable, even lyrical.

Composers

When one thinks of opera and creativity, one may naturally think first of composers – those who seem to summon music from their souls, who create something in ways that most people can’t imagine.

As in many art forms, most composers first master the styles of their times, and those with talent or genius then develop their own distinctive, recognizable styles. Early Wagner sounded like Carl Maria von Weber; early Verdi sounded like late Donizetti. Creativity and the individual voice are not necessarily harmed by thorough instruction in one’s tradition! Having developed their own styles, composers then varied in their approaches. Beethoven carried notebooks with him everywhere, so he could jot down musical themes that spontaneously occurred to him. Mozart had entire works completed in his mind before writing them down. Young Alma Deutscher says that music constantly runs through her head; for this reason she is often called “the second Mozart.” Like Chopin, both could improvise, which suggests that at least for some composers some of the time, the music arrives unbidden and unanalyzed. Some composers, such as Rossini and Donizetti, composed so rapidly that they could launch several new operas a year.

Yet even the most facile inventor faces the task of converting inspiration to completed written work. Beethoven’s labor was notoriously effortful after initial inspiration. Furthermore, opera composers must work in collaboration with librettists, impresarios, and (in past centuries) censors, complicating the process. A composer may also borrow material or styles. Some opera composers (Tchaikovsky, Bartok, Vaughan Williams, Floyd) included quotations of folk songs, or wrote original music intended to resemble folk songs.

Another question pertains to the way the composer works, its creative process – is it emotion or intellect? [Konecni \(2012\)](#) strongly asserted that composing is primarily an enterprise of “contemplation, analytical and technical skills, problem-solving, and planning – in short, reason.” This may have been true of the classical era and of the 20th century, whose 12-tone/serialism products often resemble intellectual exercises. (Perhaps he is one of those musicologists who, like Kozbelt and Simonton, make quantitative analyses of career trajectories, comparative eras of productivity, etc.). But some composers, such as Berlioz, Liszt, and Schubert, stated explicitly that indeed, their music was an expression of their own emotions. Perhaps it is a mistake to attempt to declare music solely one or the other. Tchaikovsky wrote to his patron, “What has been written with passion must now be looked upon critically, corrected, extended, and most important of all, condensed to fit the required needs of the form. One must sometimes go against the grain in this, be merciless, and destroy things that were written with love and inspiration.”

Of the hundreds of composers who have attempted the opera form, a handful rule the tops of the charts (Verdi, Mozart, Puccini, Rossini, Wagner, Richard Strauss, and Bizet). Others, famous in their own days, faded from the repertoire. [Simonton \(1998\)](#) found that an opera’s initial reception (enthusiastic or tepid) was a good (but not perfect) predictor of its success in the long term. After examining the careers of 59 classical composers ([2000a](#)), Simonton concluded that, although the acquisition of expertise over time plays a large role in the development of mastery, a composer’s career success cannot be entirely predicted by such measurable factors. It may be some comfort to creative people to realize, “The life of any creator is almost invariably an unpredictable succession of successes and failures, of hits and misses. A work that brings its creator unprecedented acclaim may be followed by an embarrassing fiasco” (p. 312).

Along with their artistic success, the social roles of composers changed over time, from being considered “the help” to their more recent status as honored celebrities. Still, all composers, no matter how creative and celebrated, have to please someone: noble patron, censor, general director, major donor, reviewers, and ultimately audiences.

Librettists

Very few composers create their own libretti – Wagner and Leoncavallo were among the exceptions. Generally, composers hire (or are assigned) a playwright or poet, who will take an existing work and revise it, deleting and adding until the text fits into a few hours on the stage. Singing takes longer than speaking, and costumes, scenery, and lighting replace description, so that much of the source material can be omitted. Subplots and minor characters may be added or deleted. Thus the librettist's creativity often involves *re-imagining*.

This sometimes requires a major leap. For instance, composer Jake Heggie was offered a commission for a new work, and contacted Terrence McNally, his collaborator on *Dead Man Walking*, for a story idea. He was daunted to hear McNally suggest Melville's sea-going novel *Moby-Dick*. A giant novel boiled down to 3 h? Luckily, Heggie kept listening. McNally suggested that the land-based scenes be eliminated and the opera take place entirely at sea. Heggie says, "I saw the twinkle in Terrence's eye and knew he had thought of a way the story could work – hugely challenging, but possible. I also knew that there was music inherently in the book and story – so if the libretto worked, the score would work" (personal communication, February 20, 2019). Heggie decided to end the opera with the novel's opening line, "Call me Ishmael" – a magnificent culminating *coup de théâtre*. Due to McNally's subsequent illness, Gene Scheer was brought on board as librettist (not the first time that a composer had more than one partner on a work), and their powerfully affecting opera, which premiered in 2010, has now been produced in twelve cities around the world, plus a DVD and a nationwide telecast.

Source Material

There are few totally new stories. In its early history, operas were typically based on stories of the gods, kings, and myths of Western civilization, though as late as the 1870s Wagner drew on Norse mythology. Traditional fairy tales stimulated others: Hansel and Gretel inspired Humperdinck's one masterpiece and Cinderella has inspired numerous composers, most recently the young prodigy Alma Deutscher in 2017.

The Bible is a storehouse for composers, as it has been for painters and poets. From the Old Testament we got, among others, Verdi's *Nabucco*, Saint-Saëns's *Samson and Dalila*, and from the Apocrypha, Floyd's *Susannah*. The New Testament has been less fruitful, presumably due to the audacity of having Jesus appear onstage. Actual history appears sometimes, as in Putz's *Silent Night*, about the spontaneous truce between German, French, and British soldiers in the trenches of World War I. Mangled history also appeared, as librettists twisted facts (and plagiarized each other) to make dramas more to their era's liking, such as Donizetti's derivative Tudor trilogy.

But the commonest source material is other Western authors. [Simonton \(2000b, p. 110\)](#) listed the Arabian Nights, Ariosto, Beaumarchais, Byron, Cervantes, Corneille, Dante, Dumas, Euripides, Goethe, Gogol, Hoffmann, Hugo, Ovid, Pushkin, Racine, Sardou, Schiller, Scott, Sophocles, Tasso, Virgil, and Voltaire. The most frequently used author is Shakespeare, whose plays have inspired over 250 operas, including those by Adam, Barber, Bellini, Berlioz, Britten, Bruch, Gounod, Halévy, Nicolai, Purcell, Rossini, Smetana, Vaughan Williams, Verdi, and Wagner.

Thus composers and librettists draw from traditions in which they are steeped and also from their own imaginations.

Singers

What do the singers do that is creative? Lyrics and music are given them; the director tells them where to stand and how to act; and the conductor sets the pace. Their creativity consists in making the character their own, skillfully deploying their vocal instruments, and artfully acting the part. Singers learn breath control, technique, transitioning from chest register to head register, and much more – not to mention learning to sing in Italian, German, French, Russian, and Czech.

According to one anthropologist who is also a busy professional opera singer, "Singing is very much like athletics, it's extraordinarily physical It's not just learning the notes and the words. Learning to sing a part in an opera is like learning an Olympic routine as an ice skater" (quoted in [Kotnik, 2008](#), p. 52). And the experience exalts the whole person: when in what Csikszentmihalyi called *flow*, "a performer experiences spontaneous, effortless performance to the exclusion of any internal or external stimuli, whereby body-subject and body-object merge, causing the music to flow out by itself" ([Oakland et al., 2014](#), p. 41).

Career trajectories can be formidably unpredictable. Vocal training for opera can take many years, with no guarantee of even a modest career. At each step, luck (good or bad, meeting the right person, falling ill at a crucial moment) makes a difference. They must resist teachers' urgings to sing higher than they should – too many teachers push mezzos and baritones to become sopranos and tenors, who get the best roles. Choosing the right roles is vital: careers have been ruined by singers accepting assignments that were not fitted for their voices. Damage to voices can also be caused by overwork. Other pressures in the opera life can delay or derail a career: illness, injury, performance anxiety, or an instance of what [Beghetto \(2014\)](#) calls "creative mortification" – a ghastly performance or a savage review.

But those who succeed enjoy a life immersed in the music they love. After their performing careers end, singers can continue being creative, becoming voice teachers, administrators (such as Beverly Sills), stage directors – or creators of their own opera companies, like Irene Dalis, founder of Opera San José.

Conductors

Conductors have an overall conception of the work. They set the orchestra's tempo (speed), dynamics (loud and soft), the emphasis on one instrument or section, the transitions between passages, making the music more lyrical, or more passionate, or more intellectual. Each member of an orchestra plays an instrument; the conductor plays the entire orchestra. Experienced conductors develop recognizable performance styles, and the eminent maestros' recordings may become classics.

Until very recently, women were not afforded the opportunity to be professional conductors. At the beginning of the 21st century, however, numerous women have made strong contributions in eminent orchestras, and practical support for emerging women conductors (and composers) exists in the forms of grants, residencies, commissions, competitions, and positions in conservatories, plus the Women's Opera Network, which supports the advancement of women in opera administration.

Stage Directors

The director's creative contribution is to imagine the opera freshly and to oversee the execution of all things and actions that will be seen on stage. He or she conceives the opera's overall interpretation for a production – whether to present it traditionally, or slightly updated, or wholly transformed by a directorial decision, such as moving Mozart's *Così fan tutte* from the late 18th century to World War I. The director may ask that a key character be interpreted differently, or that unexpected activities be performed by the chorus – or may even invent staging for the overture. He or she directs the movement of singers around the stage ("blocking"), in ways that, ideally, support the text and the music. Good staging can make an opera come to life and give singers a platform worthy of their talents. Eminent directors are those, like Zeffirelli and Ponnelle in the last century, whose productions are treasured and kept in the repertory by numerous opera companies for generations.

Some directors, on the other hand, determined to be thought "original," radically alter the opera. The first scene of *Tosca* takes place in church, where the hero Cavaradossi is finishing his painting of Mary Magdalene. One director decided to place the artist's still-wet painting flat on the floor, and instructed the performers to walk all over it, which they did. Even a non-devout viewer was shocked. Unfortunately, this was one of the milder directorial atrocities of recent decades. In a Canadian production of Handel's *Semele*, the betrothal ceremony was crashed by a two-person donkey, which reappeared during a love scene between Jupiter and Semele, flaunting a giant phallus. In case we were insufficiently repelled, chorus members engaged in nude onstage couplings as well.

These are not accidents. Kotnik (2013) observed that two German directors' stagings are "regularly accompanied by scandals, furors, uproar and sensation" (p. 306). Verdi's *Masked Ball* was once set in a men's room, with the chorus singing while sitting on toilets. Not surprisingly, the style (officially Regietheater, or "director's theatre"), became known in places as "Eurotrash." Even Wagner's own opera house in Bayreuth has encouraged it.

There were loud boos on each night of the opening week and when [German director] Frank Castorf showed his face after *Götterdämmerung*, the crowd howled in anger. The director proceeded to milk the outrage, lingering before the curtain for more than 10 minutes and inserting himself into other people's bows. To all appearances, this finely nuanced performance as Directorial Narcissist was the only characterization to which Castorf had given serious thought.

Ross (2013), p. 71.

Of course, the general directors of the opera companies have a lot to answer for by hiring directors they know are controversial. Admittedly they are trying to win audiences in a challenging environment. Director Peter Sellars said bluntly, "I'm deliberately doing something that we all need to talk about, so controversy is the job description" (Wolfe, 2015, p. C 11).

Luckily, there are dozens of talented directors working today who can successfully stage operas in a traditional fashion, or unleash magical creativity in skilled and tasteful variants. Let us close with the balanced opinion of director-impresario Lotfi Mansouri, who brought the innovation of supertitles to American opera companies: "The most important principle for a stage director to follow is that he or she must remain faithful to the spirit of the work" (Mansouri and Layton, 1982, p. 53).

Administrators

General directors (along with their artistic advisors) select the operas, conductors, stage directors and singers. They hire designers to create sets and costumes under the supervision of stage directors, forming the teams that will bring the vision to life, as much as five years hence. Marketing directors, attuned to the whims of fashion and the vicissitudes of the economy, devise seasonal advertising and long-term outreach.

Creativity is demanded of opera administrators as standard forms of marketing disappear. In the mid-twentieth century, there were three television networks; some featured shows on which opera singers performed for nationwide audiences. Favorable newspaper reviews could fill the house. The loss of these showcases, combined with staggering increases in production costs, means that

at some houses key administrators have come from the business world, not the arts. It remains to be seen how effective this tactic will be in the long run.

Opera companies today must cultivate not just a few wealthy donors, but many donors at all income levels. Opera companies must continually develop new ways to attract ticket buyers and convert them to subscribers. This quest has been assisted by resourceful authors. No fewer than 16 popular books of the 1990s were intended to educate beginners, with titles such as *Get into Opera: A Beginner's Guide*; *Who's Afraid of Opera?*; and, inevitably, *Opera for Dummies*.

But marketing strategies must be carefully considered. Administrators face a daunting task to please the various sectors of their audience. What works in one city may not succeed in another. In places, the opera season may now include perennial favorite musicals and operettas, to the consternation of traditionalists.

Administrators must also decide when to offer revivals instead of funding costly new productions, and attend to such mundane factors as the order in which their offerings are presented. Interspersing conventional and unconventional operas may please audiences but turn off the reviewers. Bundling tickets with various benefits (parking, pre-performance dinners, meeting the singers at special events, etc.) has become an effective way to enhance attendance.

In Europe, government subsidies are common: Germany has 83 opera houses with public funding, while France and Great Britain have about a dozen each. American administrators can only dream of such fiscal stability – but it comes with a price. Lotfi Mansouri remarked, “State subsidies can backfire. The companies can afford new productions and the stage directors feel they have to make their mark. That’s why there’s so much trash onstage” (personal communication, June 18, 2013).

Instead, American companies try creative maneuvers to gain audiences. San Francisco Opera offers an annual free simulcast of a live performance in the nearby baseball park – and as many as 30,000 people attend, bringing blankets and picnics. The youngest children tend to run around the infield, but are nevertheless having that all-important early exposure to opera that helps establish the audiences of the future.

Audiences

To be fully creative, a work of art must reach an audience. This is, of course, especially true in the performing arts. Opera-goers could simply sit passively and absorb the sound and story, but as [Pritzker asserts \(2007\)](#), it is possible to exert creativity even in this limited role. He defines *audience flow* as the experience of viewing a performance or reading a book “in an active and mentally engaged state that may allow insights and new perspectives to develop” (p. 110).

Furthermore, as anyone who has performed even in amateur theatricals knows, an enthusiastic, attentive audience can stimulate them to new heights, while a lukewarm one saps their energy.

Audience members are creative by agreeing to believe that the space behind the curtain is the place it purports to be and that the performers are the people they represent. They don’t care about the classic “three unities” and cheerfully accept each change of scene. They willingly surrender their sense of identity and place, and perform the magic of innocently receiving the musical offering, yet retaining the ability to distinguish their emotions from those being portrayed onstage and to critique the performance afterwards. Of course, they don’t always agree: patrons and reviewers report vastly different responses to the same production, even to the same performance, as attested by the heated discussions taking place during intermissions.

Forman (1994) places opera patrons into five classes: Snobs, who show off their knowledge of opera at every opportunity; Glitzies, who come to display their wealthy social status; Corporates, whose employers demonstrate their philanthropic values with handsome donations; Casuals, the largest group, people who appreciate music and aren’t afraid to show it; and Buffs, the “hard-core opera addicts” – devoted, knowledgeable subscribers who own, read, and listen to books on opera and recordings of operas.

Buffs are passionate fans who seek peak experiences, “collective effervescence,” and “pure musical experience [that] resembles religious mysticism, and ... virtuoso religiosity” ([Benzecry and Collins, 2014](#), p. 307). One interviewee ([Benzecry, 2012](#), p. 45) was annoyed at researchers’ questions that, to him, seemed trivial and irrelevant: “Why is it that you sociologists always ask if I go to the opera to be seen, to meet people, to see my friends, to achieve a better professional status?” he asked. “You always fail to ask me if I go because I like it or, better, because I love it.”

Reviewers

Reviewers have their own form of creativity. The best professional reviewers have had a deep understanding of the art form and some literary skill. Here are a few torrents of eloquence that opera has elicited in the past, starting with an ecstatic review, well worth reading:

Her voice commands overall phenomenal possibilities of expression. She has the profound depth of a contralto and reaches heights of glittering, alluring splendor. From the sweetest-sounding melody into the hollow groan of anguished torture, from the hellish laughter and from the shattering

depths in a siren song of unbelievable beauty ... Her interpretation fills the dimensions of the myth; the measurements of sin and penitence; of the seductress to the ignominious; of inordinate passion and desire finally restrained and subjugated.

Quoted in Riebel (2014), pp. 45–46.

Reviewers can also be uninhibited about issuing caustic takedowns, relishing their power to influence opinion. Wrote another:

Silly and inconsequential incidents and dialogues are daubed over with splotches of instrumental color without reason and without effect, except the creation of a sense of boisterous excitement and confusion ... but even here the expression is superficial and depends upon strident phrases pounded out by hitting each note a blow on the head as it escapes from the mouths of singers or the accompanying instruments.

This was H.E. Krehbiel's opinion in 1900 of *La Bohème* (quoted in Slonimsky, 1953, p. 135). Wagner's third opera elicited this spicy judgment in 1869: "*Rienzi* tastes like a mixture of Verdi and Meyerbeer pounded in a mortar until it begins to ferment" (quoted in Slonimsky, 1953, p. 232).

Reviewers' prophecies can be mortifyingly inaccurate, like this confident judgment: "*Rigoletto* is the weakest work of Verdi. It lacks melody. This opera has hardly any chance to be kept in the repertoire" (*Gazette Musicale de Paris*, 1853; quoted in Slonimsky, 1953, p. 218).

The Future of Opera

With the decline of the subscription base, waning of print newspapers, aging of audiences, and multiple other forms of entertainment competing for audiences' attention, some commentators foresee a bleak future for opera. It is some comfort to remember Rudolf Bing's famous remark, "The opera always loses money. That's as it should be. Opera has no business making money."

However, opera lovers and administrators are rising to the challenge. The Met invented live video broadcasts and reaches millions of people in over 2000 movie theatres in 70 countries. Opera administrators create special social clubs for young people (those under 30, those under 40) to benefit from people's desire to connect outside work. Schools have long been beneficiaries of opera outreach, with many companies sending singers to schools and helping students create and perform their own mini-operas. Teachers eagerly schedule classroom visits by opera outreach programs, and over a hundred opera companies in the United States supply them. This musical collaboration between music professionals and children manifests creativity on many levels, from marketing departments to singers, teachers, and the children themselves.

Today, there are several American opera companies with international stature, half a dozen major regional opera companies, and uncounted smaller companies that provide work for singers and the other opera creators, and music for their cities. According to the trade website Operabase, over 400 opera companies worldwide offer more than 25,000 performances a year. Young singers continue to enroll in conservatories and training programs. Composers continue to offer new operas. Nimble new companies, often founded by groups of singers who perform in modest (even itinerant) venues on shoestring budgets, help extend the passion for opera into the future.

Many opera professionals contend that to remain vibrant, opera must welcome new works. The president of the trade organization Opera America recently wrote, "It is essential that the art form evolve in order to thrive, that we must explore operas that are new in terms of style, subject matter, scale and venue, and that we have to look for many more artists who tell the story of today" (Scorca, 2018, pp. 24–25). Fortunately, many opera companies are doing just that – commissioning works, joining together to pay for new operas, establishing small venues for experimental works, and finding other ways to support composers.

Technology, while presenting stiff competition to opera, also offers opportunities in production and marketing, such as projections, close-ups, live transmissions, promotions on social media, archived online performances, and more. Such flexibility is not mere fashion; cultural historian Kotnik (2013) has found that "the element that ensured opera's long survival has been its adaptability to whatever historical contexts, economic situations, social conditions or cultural milieus surrounded it" (p. 321). Adaptability is, of course, creativity in action. From composers, to administrators commissioning new operas, to technicians taking advantage of new technologies to produce and promote them, to new performers lighting up the stage, to marketing departments dreaming up new ways to attract patrons, to children devising their own operas in their classrooms, creativity in the opera world is flourishing.

Introduction

In the management literature, creativity is defined as products, processes, services, or procedures that are both novel and useful (Shalley et al., 2004). What is interesting is that in this literature creativity has been conceptualized in two ways. First, creativity was considered as an outcome, ranging from minor adaptations to radical breakthroughs. As such, scholars using this conceptualization examine the creative performance of individuals and teams. Second, creativity was also viewed as a process, with researchers examining the specific processes that individuals and teams go through while attempting to develop creative outcomes.

Both approaches to creativity (i.e., as an outcome or a process) consider creativity to be a social phenomenon that is influenced by contextual factors. Until the 1980s, psychologists primarily studied creativity as a personality trait or as a cognitive process. However, conceptual work (e.g., Amabile, 1983; Woodman et al., 1993) moved the study of creativity to a more social psychological domain, highlighting the need to consider the external work context.

Amabile's componential model (1983) focused on the social psychology of creativity, arguing that creativity as a trait approach is incomplete, and in fact, creativity can be better understood as a behavior that results from particular combinations of personal characteristics and the work environment. With this model, Amabile highlighted how social and contextual factors were neglected in the creativity literature. She suggested that domain relevant knowledge, creativity relevant skills, and task motivation contribute to creative performance simultaneously and each of these components can be influenced by external contextual factors.

Similar to the componential model, the interactionist perspective proposed by Woodman et al. (1993) emphasized the role of the interaction between individual characteristics and contextual characteristics for employee creativity. Yet, they added another layer to these arguments, and suggested that creativity is a much more complex cross-level system in which individual, group, and organizational characteristics interact with each other. As an example, they suggested that an individual's creative performance depends on the interaction between team characteristics such as group norms, organizational characteristics such as the reward structure, along with individual characteristics, such as their cognitive processes.

Building on these two views, organizational scholars argued that individual characteristics are not the only determinants of creativity, but that the organizational context and the interaction between these two also can play a role in whether employees are creative or not (Shalley et al., 2004). As such, a number of contextual factors that influence creativity have been studied. This entry will briefly review the literature related to five contextual factors that have received the most attention in the management literature as potential antecedents of individual or team creativity. They are leadership, feedback and evaluation, rewards, social networks, and team composition and processes.

Organizational Factors that Impact Creativity

Leadership

To date, leadership is the most widely studied contextual factor impacting creativity. Results of a large number of studies lead to a very consistent finding that leadership positively relates to creativity as long as it is supportive and noncontrolling. This is true for a wide range of different leadership styles, such as transformational leadership, servant leadership, and ethical leadership, among other leadership styles. For example, some researchers developed and tested a model linking empowering leadership with both creative process engagement and creative performance and they found that empowered leadership positively affected psychological empowerment, which in turn influenced both intrinsic motivation and creative process engagement, and ultimately creative performance (See Leadership).

Employees with creative personalities who worked on complex jobs, and had supportive, noncontrolling supervisors had the highest creative performance. Instead of focusing on a specific leadership style, [Koseoglu et al. \(2017a\)](#) examined the role of the supervisor's own level of creativity on employee creativity. They found that subordinates' creative role identity (i.e., whether being creative is part of your work identity) is an important underlying mechanism in the relationship between supervisors' level of creativity and subordinates' creativity, and their results supported this. Research investigating the dark side of leadership for employee creativity suggests that not only can leaders' abusive supervision negatively relate to their employees' creativity, but that it can also have a cascading effect and flow down levels in the organization, undermining team members' creativity.

Feedback and Evaluation

Although there have been some conflicting empirical results, in general the common wisdom is that the effect of evaluation and feedback on creativity can be positive as long as the message conveyed is more informational than controlling. For example, [Shalley and Perry-Smith \(2001\)](#) found that the creativity of individuals expecting a judgmental evaluation was significantly lower than those expecting a developmental evaluation.

More recently, some interesting approaches examined the impact of evaluation or feedback on creativity. For example, [Yuan and Zhou \(2008\)](#) investigated the differential effect of expected external evaluation on two different stages of the creative idea production process, idea generation and idea selection/modification, and found that expected evaluation had different effects on these two stages. Specifically, during idea generation those who expected an evaluation generated a fewer number of ideas, while during idea selection/modification, those expecting an evaluation performed better in improving the idea's appropriateness. Furthermore, individuals who only expected an evaluation during the idea selection/modification stage produced the most creative ideas. [Harrison and Dossinger \(2017\)](#) explored how feedback seekers and providers in creative work find a balance between what makes feedback helpful and having the freedom to explore new ideas. They found that when seeking feedback, individuals that were more curious tended to ask more open questions, allowing them to gain more information. They also found that ambivalent feedback lead to higher acceptance of the comments, and ultimately design revisions.

Rewards

The effect of rewards on creativity has received much research attention, and most of this work has been conducted in the laboratory. However, the empirical results are typically mixed and inconsistent. While some studies found that rewards detrimentally effect creativity, other studies have found them to have a facilitative effect. In addition, there has been a great deal of controversy regarding the likely direction of the effects of rewards that are contingent on creativity. For example, [Amabile \(1983\)](#) argued that rewards contingent on being creative can serve to control individuals' behavior and lead to lowered intrinsic motivation and creativity. Others argued that rewards can have informational value and can signal personal competencies, and therefore facilitate creativity (e.g., [Eisenberger and Rhoades, 2001](#)). There is still an ongoing debate in the literature, with different studies supporting each position (See Rewards and Creativity).

Results of a meta-analysis suggested that the above conflicting findings could be due to differences between studies in terms of reward conditions and the context in which the reward is offered ([Byron and Khazanchi, 2012](#)). Specifically, across approximately 70 studies, rewards tended to increase creativity especially when individuals were aware that the reward was contingent on creative performance. In addition, some researchers suggested that the relationship between rewards and creativity can be contingent on cognitive style and job complexity. Specifically, researchers found a positive relationship between rewards and creativity for employees with an adaptive cognitive style who worked on relatively simple jobs. In contrast, they found a weak relationship between rewards and creativity for employees with an innovative cognitive style who worked on complex jobs, and a negative relationship for those who had an adaptive style and worked in complex job and those who have an innovative style working in simple job conditions (See Cognitive Styles).

Social Networks

Since employees do not work in isolation, their relationships with others in the organization can impact their creativity. Therefore, another contextual factor, the social networks of employees, was examined. Researchers found that an employee's strength of network ties (i.e., the closeness, duration, and frequency of the relationship between two actors which can range from weak to strong) and the structure of his/her network (i.e., the configuration of how one's contacts are connected to him/her and to each other) impacted his/her creativity. Researchers who focused on the characteristics of network ties primarily examined the role of tie strength, and there were conflicting results. For example, having a large number of weak relationships was found more beneficial for collecting a diverse set of non-redundant information and perspectives from various contacts rather than investing in fewer but stronger relationships ([Perry-Smith and Shalley, 2003](#)) since individuals have limited time and resources. On the other hand, other researchers suggested that strong relationships are more beneficial for creative performance, because gathering information from people necessitates a sense of trust and cohesiveness. Integrating these two opposing views together, some researchers argued that the importance of strong versus weak ties depends on the stage of the creative process. For instance, while a higher number of weak ties can facilitate idea generation, a higher number of strong ties can be beneficial for idea elaboration.

The second network characteristic that impacted employee creativity was network structure. Researchers studied either the local network of individuals, that only includes their immediate contacts (i.e., ego networks), or their global network, which is their position in the entire organizational network. The local network structure of an ego network can vary in its level of density. Burt (1992) introduced the importance of brokering structural holes that deal with whether one is connected to two individuals who are not connected to each other. If an individual has a lot of structural holes in his/her ego network (i.e., contacts who are not connected to each other but only connected to the ego), this is considered to be a “sparse” network with lower density. In addition, the more the contacts of an individual are already connected to each other, the fewer structural holes in his/her ego network and the network becomes denser.

Just like the tie strength arguments, there is an ongoing debate on the role of network density for employee creativity. The benefit of serving as a bridge over a structural hole and connecting two unconnected contacts is in getting non-redundant information and diverse perspectives from both contacts that have been found to facilitate creativity (Burt, 1992). An individual with a sparse network structure may have the opportunity to collect a great deal of diverse and non-redundant information, and therefore have higher creative performance. Another group of researchers claimed that closure within a network results in trust-based relationships that enhance information transfer among actors. These researchers stated that the trust and reciprocity provided by dense networks make diverse information more accessible due to enhanced cooperation and collaboration, since individuals will feel safer sharing their opinions in their work environment, which can eventually lead to better creative performance.

Some studies combined these two conflicting arguments, looking at the entire innovation process. For example, some researchers found that sparse ties can be advantageous during the creative process, but when it comes to the diffusion of those ideas and moving through to innovation, it is better to have dense relationships. Another group of researchers studied the innovation process under three stages: idea generation, development, and refinement. They found that density should increase in each stage, starting from idea generation through idea refinement. Meta-analysis findings suggest that network density has negative effects on employee innovation, and brokerage has the strongest positive effect compared to the effects of tie strength, network size, and diversity (Baer et al., 2015).

When it comes to an individual's location in the global network structure, in their conceptual piece Perry-Smith and Shalley (2003) argued that employees in a peripheral location who have a higher number of connections outside of the organizational network are more creative because they have access to non-redundant information that is not shared by others in the organization. Yet, they also argued that as a person performs creatively, their popularity in the organization increases, and this can cause them to move from a peripheral position to a more central position over time. Other researchers further found that the most creative individuals were at an intermediate position between the center and the periphery because each position has different benefits. For example, while being close to the center can help with getting one's creative ideas recognized and implemented, peripheral locations provide access to outside organizational contacts with non-redundant information.

Team Composition and Team Processes

Although working alone can enhance creativity, in organizational settings, employees typically work in teams. Therefore, it is essential to understand how teams can be creative, but to date the organizational creativity literature is still predominated by studies on individual creativity.

Team creativity is a collective phenomenon that involves members defining problems, generating ideas, and attempting new ways of solving the problems they face at work (Gilson and Shalley, 2004). As such, although the average of each team member's creative performance and the team's overall creative performance has a positive relationship, team creativity is not just simply an aggregate of individual creativity. Rather, team creativity is a function of the interaction between team members and the contextual environment in which they work Woodman et al. (1993). Similar to individual creativity, team creativity also can be considered as an outcome or a process. Research examining antecedents of team creativity found that both team composition and team processes can influence team creativity.

Perhaps the most frequently studied team compositional characteristic is team diversity. There are two types of diversity, deep level diversity (or cognitive diversity) which is based on non-observable differences among team members such as functional background or abilities; and surface level diversity based on observable characteristics such as demographic differences. The research indicated mixed findings on the relationship between deep level diversity and team creativity. On the one hand researchers found a positive relationship, arguing that a greater range of perspectives, ideas, and abilities result in higher quality solutions. On the other hand, some researchers found that conflict, which can be an outcome of diversity, can hurt team creativity due to a lack of information sharing among members. Some researchers added that conflict had a stronger impact at earlier stages of the team life cycle and could become irrelevant at later stages. In order to explain these contradictory findings, van Knippenberg et al. (2004) adopted the categorization elaboration model of diversity, suggesting that task diversity will be beneficial for team creativity only if team members can take advantage of this diversity. For example, researchers found that team diversity had a positive impact on team creativity as long as team members took advantage of diversity by engaging in perspective taking, as this lead to the successful elaboration of the diverse information held by each team member. Relationship conflict based on interpersonal incompatibilities among team members, could be an output of surface level diversity, and lead to a lack of information exchange between team members. Therefore, research showed that surface level diversity negatively impacted team creativity.

Meta-analytic evidence suggested that goal interdependence is one of the strongest antecedents of team creativity, meaning that teams with a common goal of being creative are the most creative. Relatedly, it was found that teams with high goal and task

interdependence were more likely to engage in creative processes. Another critical team compositional factor is team size. Having more members can potentially lead to more diverse information, resulting in higher levels of team creativity, yet communication problems and social loafing can arise due to the larger team size, impeding creativity. Focusing on innovations in the comic book industry, researchers found that having a higher number of creative team members affected the variance of a product's innovation, with the outcome being either extremely creative or extremely non-creative.

Team processes also play an important role for team creativity. Team members who shared knowledge and ideas were able to make new connections between previously unconnected ideas. Team learning which involved behaviors such as feedback seeking and reflecting on previous results played a critical role in team creativity.

A series of laboratory experiments suggested that when teams learned from their own experiences, they became more creative as they kept working as a team on new tasks. This relationship was mediated by developing a transactive memory system, which is defined as a collective learning and memory system used to encode, store, retrieve and communicate group knowledge. Furthermore, teams with prior experience working together generated outcomes that were more creative since they had an easier time communicating with each other. However, collaborating repeatedly as a team can start to hurt team creativity if the members stop focusing on their differences in ideas and perspectives and become more stable. In order to overcome this possibility, new team members could be added to the team or interventions could be used. Yet, it should be noted that the timing of these interventions could play a role as well. For example, deadline changes at the very last minute, or workload changes any time after the mid-point of the original assigned task time can be detrimental to team creativity (Koseoglu et al., 2017b) (See Teams).

Concluding Remarks

In the field of management, a number of studies examined the effect of contextual factors on employee creativity, such as leadership, feedback and evaluation, rewards, social networks, and team composition and processes. However, there is still a need for more work in this area. In particular, there is still not a full picture of how these five contextual factors influence employee creativity. In addition, there are many contextual factors yet to be examined in any systematic way, as well as their potential interaction with different personal characteristics to impact employee creativity.

Glossary

Fanfic A variety of literacy practices, including producing short stories, poetry, lyrics, and fantasy worlds, among others, that express identification with a fandom community.

Juvenalia Artifacts of childhood, often including toys, games, and products of creative engagement, such as written stories and childhood art pieces.

Paracosm A consistently maintained, and often deeply cared for, personal imaginary world created during childhood or early adolescence. The act of creating and maintaining a paracosm is sometimes referred to as “worldplay.”

Transnarrative A story that exists separately from any one media presentation, and as such may be engaged with through multiple venues, including movies, books, games, and online discussions.

World-building The process of constructing a fictional world as a setting or as a creative product in itself. World-building can be a solitary activity or the object of social collaboration. It is sometimes related to fan fiction writing.

Introduction

There is a lonely sort of splendor to be appreciated in the fantasy worlds of childhood, when the capacity for mythical thinking burns at its very brightest. The curious and imaginative sometimes develop raw and elegant demonstrations of the human potential to envelop the whole of humanity’s limited experience in a sense of abiding wonder.

It was in an effort to preserve these nostalgic treasures, to capture imagined vistas like “flies in amber,” that retired BBC producer Robert Silvey and retired psychiatrist Stephen MacKeith set out, in the latter days of the 1970s, to collect and categorize the personal accounts of roughly five dozen individuals who still remembered with intensity the worlds they had invented as children (Silvey and MacKeith, 1988, pp. 173–175). This was the first study of the paracosm initiated.

From the very beginning this research was unusual. It was not the result of an ambitious young scholar nor the product of an established developmental psychologist. Instead, it was a deeply personal, heartfelt attempt on behalf of an elderly, educated, and arguably amateur researcher to simply locate others in the world who shared his enthusiasm for the imagination of his childhood (Cohen and MacKeith, 1991, pp. 11–14). So, rather than early stories of pilot studies and participant sampling, there are tales of Silvey’s expository letters posted in *The Author* and the *Observer* (Silvey and MacKeith, 1988, p. 175). And, rather than making arguments for generalizability of their findings and emphasizing the broad applicability of the work, the authors made statements about how limited and private their findings were (1988, p. 177), going so far as to later warn parents away from discussing suspected paracosms with their children (Cohen and MacKeith, 1991, p. 23).

However, in seeking to gather the first paracosms, Silvey’s study called to inquiry a topic which had been theretofore largely elusive in our understanding of the development of the imagination, and which, at some level, contradicted established notions of childhood cognition (Cohen and MacKeith, 1991). He also set the tone for the emotional character of the work, which still bears the markings of attention to care, respect, admiration, and deep connection through imagination, such that even when reading

modern paracosmic accounts like those of Root-Bernstein's *M* (see [Root-Bernstein, 2009](#), pp. 601–602), it is easy to comprehend from the beginning that the unnamed participant was not treated as a random encounter, but rather like someone that the author had a close relationship with. (And indeed, *M* was revealed in later writings to be Root-Bernstein's daughter Meredith [[Root-Bernstein, 2014](#), pp. 3–4].)

This is significant because not all paracosms have been described by living persons. Indeed, some of the most famous examples of paracosmic imagination have been taken from biographical accounts and historical documentation of socially, intellectually, or artistically eminent individuals, including C.S. Lewis, Christopher Isherwood, and Friedrich Nietzsche ([Silvey and MacKeith, 1988](#), pp. 191–194). And yet, that feeling of intimacy—of a shared implicit understanding communicated through a mutual reverence for the imagination—prevails. In the introduction of [Wolf's \(2012\)](#) book, for example, the author made an argument for the intensity and emotive power that imaginary worlds can command in the experience of those who have created them, noting that “L. Frank Baum's last words on his deathbed were reportedly ‘Now we can cross the Shifting Sands’.” The tombstone for J.R.R. Tolkien and his wife Edith contains their own names as well as those of Beren and Luthien” (2012, p. 5). Wolf then, in a manner that is highly characteristic of this work, reflected on the role of imaginary worlds in his own life, recounting early experiences with LEGO and animation, as well as how he was drawn to the imaginary worlds of sci-fi and fantasy from a young age (2012, pp. 5–6).

Still, it is not in reverence alone that paracosm research has endured. A constant complement to the work of gathering new accounts of imaginary worlds is a desire to answer questions about their influence and meaning. Various approaches comprise separate branches in paracosm research, following a loosely historical pathway from the formative era of the 1980s to later divergences encompassing both paracosm investigations from the vantage of creative research and transnarrative studies. In the following sections, each of these three approaches will be discussed, highlighting their efforts to contextualize the paracosm from various social and ideological positions, as well as their contribution to overall understanding of the paracosm as a unique force in the lives of certain creative individuals.

Formative Studies of the Paracosm

As mentioned previously, the origin of paracosm research as it has been conceptualized in the modern era was to be found in the writings of [MacKeith \(1983\)](#), [Silvey and MacKeith \(1988\)](#), and [Cohen and MacKeith \(1991\)](#). Prior to this, there had existed a small, but not inconsiderable, body of literature dedicated to preserving certain childhood imaginings as a form of bibliographic juvenalia, showcasing the most noteworthy artifacts of a deeply personal type of youth literature. These paracosms tended to date no further back than roughly the late 1700s, with the earliest recorded historical paracosm belonging to Thomas de Quincey who was born in 1785 ([Silvey and MacKeith, 1988](#)). Many of these imaginary worlds were, by virtue of the zeitgeist in the era of their construction, strongly inspired by British colonialist ideologies and were contextualized by elements of imperialism, social hierarchy, and exoticism (see [Harty, 2007](#) for discussion).

This is made clear when one considers the details of C.S. Lewis's imaginary worlds of “India” and “Animal-Land,” for example, or his later world of “Boxen” which were rife with mixed “medieval and Victorian trappings” and led by a frog named “Lord Big” ([Root-Bernstein, 2014](#)). These ideals are also easily found in the shared worlds of the Brontë siblings, “Glass Town,” “Angria,” and “Gondal,” which were full of the children's shared interpretations of changing social, scientific, and moral ideals which had been inspired by their well-read upbringing, and which shaped their later works in a myriad of direct and indirect ways ([Cohen and MacKeith, 1991](#)).

There is even cause to believe that the social changes of Victorian era might, in themselves, have been a catalyst for the rise of paracosmic imaginings. [Harty \(2007\)](#) argued that emergence of the Victorian paracosm was likely the consequence of the concurrent rise of colonialist policies of the Western culture, the development of literary Romanticism, and the production of fantasy stories aimed at children:

In the second half of the nineteenth-century, the cultural agenda shifted, and paracosms were consequently relocated. Continuing the Romantic discourse of childhood, expanding and emphasizing its Neverland quality, during the Victorian era, a “golden age” of children's literature, the paracosms imagined by children were converted by adults into texts for children. [...] Through Romanticism's mapping of childhood, it became an island, a space apart. This map was subsequently internalized. Victorian childhood became an island embedded within the child

[Harty \(2007\)](#), pp. 232–233.

As illuminating as the Victorian perspective offered through lens of children's imagined worlds might be, however, it is important to note that in his first article, [MacKeith \(1983\)](#) made only a passing mention of his selection of historical paracosms, emphasizing instead the private worlds he had collected from ordinary people in his contemporaneous participant population. It was only later that [Silvey and MacKeith \(1988\)](#) included written summaries of these accounts, reasoning that “evidence from literary sources” would benefit paracosm research, in part, because “Almost all of [the historical paracosmists] became famous, or at least well-known. The ordinary reader already knows something about their later lives, and has easy access to further information about them” (1988, pp. 190–191).

By incorporating historical accounts of paracosms into their research in this manner, [Silvey and MacKeith \(1988\)](#) appeared to have been making an appeal to eminence—specifically the literary eminence associated with celebrated writers, poets, and thinkers

of that era—and incorporating the notion, more or less explicitly, that creating the paracosm may be an influence on later literary acclaim. As such, in their choice to examine the personal records of imaginary worlds present in the biographical histories of famous writers, [Silvey and MacKeith \(1988\)](#) were, as a corollary, appealing to the social position of the authors to help convey a sense of the value of the paracosm. In so doing, they appear to have systematically adopted reference to eminent imaginary worlds as an essential facet of paracosmic research.

Indeed, almost no later study or account of paracosmic imagining exists without some reference to this appeal to an eminent paracosm (cf., [Root-Bernstein, 2014](#); [Wolf, 2012](#)), which is ironic given that the early intention of the research was to serve as “a rich source for understanding how children’s imaginations can work and can develop among those who don’t go on to make glittering creative careers” ([Cohen and MacKeith, 1991](#), p. 22). Even so, given their persistent, overriding goal of cataloging paracosms ([MacKeith, 1983](#), p. 263; [Silvey and MacKeith, 1988](#), p. 174; [Cohen and MacKeith, 1991](#), p. 22), this digression into historical paracosms remained logically consistent, as it was, in some sense, just another corpus to be utilized in the refinement of a classification method—and, in fact, historical paracosms were ordered alongside others in [Silvey and MacKeith’s \(1988\)](#) study.

And it was in this way, more generally, that much of the formative paracosm research functioned. Paracosms were collected and they were categorized, with attention given to underlying questions of how paracosms fit together and relatively little concern for why they came about. As such, multiple classificatory systems were developed, each with varying degrees of relevance to the organization of material and dimensions of personal expression. These included a group of paracosmic accounts by theme ([MacKeith, 1983](#), p. 265) which later ordered their whole contemporaneous sample of paracosms ([Cohen and MacKeith, 1991](#)), the thematic characteristics of the paracosmic play, identified as four underlying “dimensions” ([Silvey and MacKeith, 1988](#), p. 185), and the personality characteristics of paracosmists, which were determined by the frequency by which participants endorsed adjectives that they believed identified themselves ([Silvey and MacKeith, 1988](#), p. 187).

Additionally, and most contentiously, [Cohen and MacKeith \(1991\)](#) presented a completed classification system which culminated the age- and development-oriented theories first proposed in [MacKeith \(1983\)](#). This developmental schema of paracosmic imaginings located paracosms relative to other types of imaginative content ([Cohen and MacKeith, 1991](#), p. 109) and expressed according to age groups in terms of their likelihood of engagement by group, with ages ranging from 3–18, wherein there was increasing occurrence of paracosmic play into late childhood and early adolescence, peaking around age 9 ([Cohen and MacKeith, 1991](#), p. 110). In so doing, they made plain their awareness that this organization of evidence would contravene established theories of the development of fantasy play ([Cohen and MacKeith, 1991](#), pp. 14–16), which had theorized that normal fantasy play should come to a close around age 7, and should not continue at all into adolescence. This is particularly noteworthy for the reason that this research presaged the more recent work of researchers like [Smith and Lillard \(2012\)](#) wherein there would accumulate a significant amount of evidence, via retrospective reporting, to support the position that fantasy play could continue beyond late childhood.

So, what to make of this rambling history of the formative study of paracosms? Perhaps it is this: That the studies of [MacKeith \(1983\)](#), [Silvey and MacKeith \(1988\)](#), and [Cohen and MacKeith \(1991\)](#) had their greatest impact by creating precedent for works to follow. In consequence of their desire to cast a wide net, researchers in this strand sought out all paracosms that were available to them, incorporating both contemporaneous and historical accounts. In so doing, they anchored understanding of the historical paracosm to the Victorian ideologies which pervaded written childhood accounts—that paracosms were exotic places, often to be mapped, which could give rise to fabulous romantic cultures and individuals. At the same time, their appeal to eminent paracosms connected this work inexorably, if perhaps unintentionally, to evocative elements of creative genius and, implicitly, to the potential development thereof. Finally, efforts to systematize paracosms according to characteristics of the imaginary places themselves, and the people who bore them, set the standard for discourse about paracosms—that they were to be defined on the basis of their contents and explored relative to their role in aspects of human development, most especially those of fantasy play and the creative imagination.

Studies of the Creative Paracosm

Starting with the work of [Robert Root-Bernstein and Michelle Root-Bernstein \(2006\)](#) and continuing in the writings of [M. Root-Bernstein \(2009, 2014\)](#), there was a revival of the study of paracosms which hewed to the overarching notion that the creation of paracosms, or “worldplay” ([Root-Bernstein and Root-Bernstein, 2006](#), p. 405), could be a sign of exceptional creativity and could, through engagement and participation, serve as a facilitator of creative thinking.

Across this strand of research, it would be difficult not to credit the appeal to eminence found in earlier, formative studies of the topic as a fundamental motivation for the work: Prior to taking up paracosms, one area that had attracted the Root-Bernstein’s attention was the way that imagination, playfulness, and creative thinking influenced highly successful and award-winning scientists (see, for example, [Root-Bernstein and Root-Bernstein, 1999](#)). And it was arguably the intention of the authors to rebut the putative status of the paracosm as it had been understood through the turn of the new millennium in those very first studies—that is to say, they were rebuking the interpretation of paracosms as primarily the product of the imagination of ordinary people (as in [Cohen and MacKeith, 1991](#)).

As such, [Root-Bernstein and Root-Bernstein’s \(2006\)](#) method of investigation followed from the creation of a survey to identify the prevalence of paracosmic imagining based on criteria provided in [Silvey and MacKeith \(1988\)](#) and [Cohen and MacKeith \(1991\)](#) that was then offered to individuals in two participant sample groups: In the first case, the survey was completed by young adults

attending courses at Michigan State University (MSU), and in the second case, the survey was offered to recipients of the prestigious MacArthur Fellowship, an award given by anonymous nomination to individuals with “extraordinary originality and exceptional promise” (Root-Bernstein and Root-Bernstein, 2006, p. 407). Group comparison data demonstrated that engaging with paracosms was nearly twice as common among MacArthur Fellows (a prevalence rate of 5%–26%, based on criteria restrictions) when compared to MSU students (a prevalence rate of 3%–12%) (2006, pp. 409–411).

Later works contextualized these findings, developing the position that paracosms were indicators of early creative giftedness and that they might, more so, serve as means for the facilitation of adult creativity—as made plain in Root-Bernstein (2009), wherein the author stated:

This re-evaluation of childhood worldplay in terms of adult creative endeavor sets aright certain misconceptions of worldplay in earlier research. Among adults recognized for creative giftedness, worldplay may, at a maximum, figure in childhood play in as many as one out of four. [...] The enduring benefit to adults of childhood worldplay does not lie necessarily or only in an early immersion in technical skills such as writing or drawing. It lies, as well, in the early immersion in self-prescribed “learning laboratories,” in self-taught creative behaviors and in self-nurtured attributes of creative personality

Root-Bernstein (2009), p. 608.

It is important to highlight here that the argument for the inherent creativity of worldplay activities represented a dramatic shift in the representation of the paracosm: Hereafter, they were not cast as the unusual product of a certain trajectory in the development of childhood fantasy play (as in Cohen and MacKeith, 1991, pp. 107–111). Instead they were thought to serve a purpose in the development of the creative imagination, and that a meaningful act of creating fantasy worlds could be capitalized on in such a way as to potentially improve creative performance, and, as a corollary, fundamental thinking skills necessary for innovation among all children (as in Root-Bernstein, 2014).

This idea has since found resonance with advocates who promote the importance of play and imagination as vital components in cognitive development for the sciences. Osterblom et al. (2015), for example, have utilized the paracosm as an exemplar of the capacity of great scientific thinkers to seek alternatives to orthodox worldviews, arguing that “the bedrock of creativity, among both artists and scientists, is the questioning and challenging of perceived reality and received wisdom” (2015, p. 16). They argued that paracosms can serve as a vehicle to embrace that challenge. Likewise, Russ’s (2016) article on the topic of the development of adult creativity drew a similar connection between paracosmic play in childhood and the expression of artistic and scientific creativity in adulthood, indicating that the mental states of paracosmic play tended to echo those of adults engaged in creative activities.

More broadly, the arguments for “playful learning” presented in Root-Bernstein’s (2014) book promoted a systematic inclusion of paracosmic imagining as a complement to educational activities. This effort highlighted the experiences of Deborah Meier, whose work in education, she believed, emulated the story and structure of paracosmic imagining (2014, p. 159), as well as accounts of more direct attempts to include imagination, play, and paracosmic world-building into school curricula through efforts like those of Richard Murphy and his *Imaginary Worlds* experiment (2014, p. 162).

And yet, even in spite of the opportunities that these methods might hold as means of improving education, there are causes to moderate expectations for the types of outcomes that a paracosm or imagination-based curriculum can produce. In their (2018) study, Taylor, Mottweiler, Aguiar, Naylor, and Levernier returned to the practice of gathering contemporaneous accounts of paracosms; however, in this case, the researchers mitigated the possibility of retrospective bias by interviewing children ages 8–12. Across their related studies, Taylor et al. (2018) investigated multiple indicators of creative thinking using a variety of assessments, measuring creativity in a diverse manner. They also assessed indicators of the cognitive states and capacities of their participants, including a coping strategies assessment, an inhibitory control assessment, and a receptive vocabulary measure. Their findings indicated that paracosmist children were more likely to display a greater proclivity toward creativity in measures of story-based creative thinking, but—most importantly—their participants displayed no other stable pattern of performance differences among other indicators of creative thinking.

This later evidence against a generalized benefit to creative thinking provided by the act of paracosmic play has, in effect, set a higher standard for future work that would hope to cast worldplay as a meaningful contributor to innovation in the arts and sciences. It supports the implication that future exponents of the educational value of the paracosm must contend with possibility—as Lillard et al. (2013) have articulated—that researchers who take up topics in areas of fantasy play and imagination should take care not to unintentionally bias their results to favor the causal efficacy of fantasy play, operating under assumptions which afford a privileged position to the “power of play” in support of a positive “play ethos” (2013, p. 4). How future researchers who seek a deeper understanding of the paracosm from the worldplay perspective will accommodate methods that incorporate more rigorous, systematic data collection and analysis procedures will doubtlessly influence the character of further research.

The Social Paracosm

The research perspective articulated in this final section does not have a definite series of active proponents, nor does it emerge from a disciplined selection of criteria for the developmental conditions or cognitive utility of the paracosm; rather, it is inspired by an assortment of findings which contradict the social role of the paracosm as it was originally envisioned. Initially, Cohen and

MacKeith (1991) set the precedent that paracosms were “private worlds of childhood”; that a paracosm was often, though not exclusively, the product of a single young person, or shared by a few siblings (1991, p. 38). So, what to make of findings demonstrating that nearly 40% of paracosmists share a world with other people (Taylor et al., 2018)? And, more to the point, what might paracosmic play look like if it could be conceived of as a social medium?

Although there has yet to be an empirical investigation constructed such that the social role(s) of a variety of shared paracosms across childhood contexts have constituted the sole topic of a study—a condition which may limit the generalizability of our current understanding—it is worth attending to the framework by which authors like Wolf (2012) and Angles (2018) have oriented the essential notion of the shared paracosm in the wider space of the development of imaginary worlds as a human endeavor. Wolf (2012), for example, incorporated paracosms into his synthetic concept of “sub-creation” with little hesitation, invoking the act of “world-building” as an intermediary, then accepting wholesale that paracosms, as imaginative world-building activities, were examples of sub-creation. Similarly, Angles (2018) broadly integrated themes in the storytelling and fantasy world-building aspects of paracosmic play to develop tactics that would allow for “imaginative explorations of, and design for speculative environments, in response to, and preparation for, challenging situations” (Angles, 2018, p. 4).

Unlike the case for extant paracosm research—focused largely on solitary fantasy play—research into activities related to world-building have a clear connection to topics of social organization, social identity development, and the interactive role of participants and presenters. World-building activities can take a variety of forms, ranging from the world creation which frames live-action role-playing, tabletop roleplaying gaming, alternate reality gaming, and the creation of constructed worlds for the purposes of fiction writing. They are the basis for many activities by which individuals express their interest in fantasy in a social setting, utilizing their ability to take up roles in an established fantasy world as a means of self-expression and creative engagement, some of which include the writing of fan fiction and fan art. While not explicitly limited to a single culture, context, or way of life, there is a greater tendency to experience these kinds of activities more often in Geek culture venues due to the fact that passionate interaction with fiction is a common avocational occupation among people who identify with that subculture.

It is important to note that interaction with fantasy through world-building activities is not limited to real-world venues, nor to one particular form of expression. World-building is mutable, transcending a single medium or mode of interaction. These sorts of fantasy-based creative activities embody the concept of “transmedia storytelling” (Jenkins, 2007) in which any specific media format serves as one of many “windows” to access the “world” that is the true “object” of an individual’s interaction with the fictional narrative (Wolf, 2012, p. 247). In this way, a richly realized imaginary world, paracosms or otherwise, might reflect incorporation of—and engagement with—the many fantasy worlds prevalent in modern society which are increasingly characterized by their capacity to encompass many sources, a variety of tellings, and different media formats.

Thus an interested individual could easily find multiple avenues of fantasy interaction with the fictional world of *Harry Potter*—as just one of many examples—via roleplaying forums on Discord (see “Harry Potter RP”, 2019) and fan fiction writing circles (see “Harry Potter Communities”, 2019). This contributes to the notion that any young person interested in the world of *Harry Potter* could meaningfully invest their time, passion, and imagination to the creation of a personal interpretation of the world of *Harry Potter* that would be functionally indistinguishable from the paracosms recorded in the early literature: The interpreted world could contain novel creations in location, substance, orientation, and social interaction, being wholly or partially the independent expression of a single, individual young person’s imagination. And yet, because of the transmedia nature of the *Harry Potter* world as it now exists, it is possible for young people to go further with their creation if they should so choose, and conveniently share, their private imaginary world with others in ways that might allow them to also contribute to the evolution of a collective imagining of the world with others, bridging individual paracosms through the social act of world-building.

And so, what might be the implications for adopting the transmedia perspective as a future venue for paracosm research? This is, at present, unclear. However, there appear to be enough similarities between the shared paracosm and other forms of transmedia storytelling to hazard some early questions: First, if one accepts that some paracosms may be shared among individuals and that others may be constructed by an individual just for themselves, does this imply two distinct uses of the paracosm? Or might there be a continuum of paracosmic social engagement? Do individuals inclined toward the social paracosm experience the development of fantasy play differently than those who have experienced a solitary paracosm? Might there be a cultural or ideological agent (possibly, for example, an inverse of the play ethos) that would inhibit social paracosmic play? And, furthermore, might it be assumed that there could be variance in the developmental impact of shared versus solitary paracosmic play? Does, for example, social paracosmic play naturally extend into a tendency to engage with other forms of transmedia storytelling in adolescence and adulthood? It is hoped that future researchers continuing in this framework might be able to approach some or all of these questions and provide some greater insight into the, as yet, poorly understood social world of contemporary paracosmists.

Conclusion

Nearly half a century has passed since Robert Silvey first set out to explain the imaginary world that had so occupied and enriched his own childhood. Since that time, much has been learned about these paracosms—their affective character, their duration, their development, and the central role that they can play in the lives of young people are a few significant insights. Based on the empirical work of Robert and Michelle Root-Bernstein, there is a perspective that the paracosm is related to learning, cognition, and intellectual giftedness, and that, furthermore, it is possible to utilize the paracosms itself as a medium for facilitating meaningful instruction. Historically, these insights have constituted the majority of research available on the topic of private solitary worlds

of childhood, and while the perspectives differ in a few key ways, both the work of Silvey and the Root-Bernstein remains the foundation to help understanding of this type of unusual imaginative activity.

Even so, there remain a number of unanswered questions yet to be addressed by research, not the least of which is the proposition that the social nature of world-building—a method of engaging creatively with fantasy that has grown along with the spread of transmedia narratives—may influence (and be influenced by) the formation and expression of individual paracosms. With the advancement of communication technology and the expanding cultural significance of sophisticated fantasy and sci-fi settings, it appears possible that the experience of solitary paracosm as it had existed in previous times, and which was so keenly felt by Silvey throughout his life, may be evolving in ways that could not have been predicted in prior eras: Thus, perhaps, it could be said that the notion of the 21st-century paracosm has, in itself, become an unexplored frontier on the horizon of imagination.

Introduction

Creativity can be analyzed through various psychological dimensions. Personality is one of the earliest and most prominent approaches. The extensive study on creative personality has documented two main theoretical perspectives. The first is the classical approach that focuses on fixed traits or dimensions (Domino, 1970; Gough, 1979). To test the usefulness of this approach, researchers collected data from people in certain occupations. They examined if personality attributes may explain how some individuals are more creative than others within a certain domain. Those studies indicated that creative people tend to be autonomous, independent, contrarian, non-conformist, and challenging the status-quo.

On implication of such conceptualization of creative personality is that some of those characteristics may be the characteristics of people with mental illness or those having the propensity to develop one. In fact, the link between creativity and mental illness attracted much attention. Specifically, creativity has been studied among psychotic patients and occasionally found to be linked to pathological traits (Eysenck, 1995). Although there is evidence for creativity's relevance to psychoticism, the vast majority of researchers tend to study creativity's relationship with non-pathological traits such as adaptability, sensitivity, originality, receptivity, perseverance, independence, tolerance towards frustration or uncertainty, openness to experience and self-discipline (Guilford, 1950).

The second approach is based on the paradigm of complexity and focuses on the dynamic coexistence of opposing tendencies (Csikszentmihalyi, 1996; Torrance and Hall, 1980). Creative personalities are defined as having the ability to modify one's own actions by embracing contradictory attitudes. From this perspective, creative people have a "paradoxical personality".

Paradoxical Personality

Human beings originally possess multiple contradictory qualities. However, these qualities either become fixed or weakened as they develop. Once weakened, only one pole of the contradiction will be expressed and turned into a particular personality trait. Therefore, a large majority of people do not have both poles or exemplify the notion of coexistence of paradoxical tendencies and thoughts. They are usually considered as either conservative or rebellious, passionate or objective, humble or proud, not both. Creative people, by contrast, usually retain both poles and express a wide range of attributes under different situations, which results in the notion of paradoxical personality (Csikszentmihalyi, 1996). When such paradoxical tendencies are found together in one person, the term paradoxical is used to describe him or her. It is called as paradox because it seems self-contradictory, contrary to received opinion, and against our expectations. A paradoxical personality involves a wide array of personality styles in different contexts. Thereby, behavior fluctuates around a multiplicity of polarized attributes instead of settling into static traits.

It has been also hypothesized that the number of paradoxical traits, the complexity of personality, and the degree of creativity are related. The more paradoxical features are present in the same person, the more complex his or her personality will be, and therefore, his or her creativity will be more developed.

The creativity paradox or paradoxical creativity can be defined as the simultaneous coexistence in creativity of psychological elements that seem logically mutually contradictory. It is important to note that personality characteristics considered as important for creativity seem to be contradictory. For instance, critical and destructive attitudes may exist with constructive problem solving, self-criticism may be with self-confidence, fantasy may be with a strong sense of reality, and stereotypic masculinity and femininity (autonomy, self-confidence, and toughness vs. sensitive, intuitive and responsible) may exist together. According to the systems approach, distinction is not same as separation. When we distinguish between two things, we say there is a difference between them, but they are not necessarily separated or opposed. This is best exemplified by the distinction between yin and yang. Even though they are distinct, they are not separated. A systems approach stresses that such parts are interrelated and provide potentially generative interaction. The polarities in paradoxical personalities should be treated in this way. There is a cybernetic process in

creativity that goes beyond simple dualities. According to Barron, paradox is an aspect of humanness "... without stability, we can have no flexibility; without discipline, no freedom; without knowledge, no creation; without subjectivity, no objectivity" (1995, p. 35). Such dualities should be accepted as having a cybernetic relationship instead of opposites.

Paradoxes and Creative Personality

A creative personality can be described as a constellation and complex. No one trait leads directly to creativity. Instead, many of them, and their complicated interactions, bring about creativity (Runco, 2014). This is best observed in the paradoxical personalities mentioned earlier by several researchers. The research on paradoxical creativity is based mainly on case studies, currently showing scarce psychometric developments.

MacKinnon (1962) provided an interesting example of paradoxical personality in his study on architects. He found that creative architects are self-aware, open to emotions and express a wide range of interests. Even though the sample was composed of male architects and the data was collected when sex-role stereotypes were fairly polarized, they were found to be open to feminine options in their thoughts and behaviors. Based on such findings, MacKinnon concluded the importance of tolerating and integrating opposing values.

It is acceptable that the creative work itself provide the coexistence of conflicting traits. MacKinnon (1962, p. 490) stated, "it would appear that the creative person has the capacity to tolerate the tension that strong opposing values create in him, and in his creative striving he effects some reconciliation of them." Many creative people are aware of their conflicting traits or thoughts, and they utilize this because they know that it contributes to their creativity.

According to Barron and Harrington, people with paradoxical personalities are able to resolve antithesis or accommodate obviously contradictory traits in their self-concepts. Barron (1963) described a creative person as being, "more primitive and more cultivated, more destructive and more constructive, occasionally crazier and yet adamantly saner, than the average person" (p. 234). Similarly, Maslow (1976) asserted that creative people have the ability to manage conscious and unconscious and primary and secondary processes simultaneously. He also believes that the resolution of dichotomies allows creative people to integrate two opposite traits in a new synthesis. He listed pairs of traits, including altruism and hedonism, instinct and reason, duty and pleasure, and work and play. McMullan (1976) stated that creative individuals can jointly access two modes of thinking. He addressed the conflict between eight paradoxical characteristics: delay in closure versus systematic closure, divergent versus convergent thought, relaxation versus attention, discontented versus constructive attitudes, mindless perception versus understanding based on memory, emotional involvement versus detachment, disinterested motivation versus selfish motivation, and humble versus confident self-concept. Torrance and Hall (1980) also proposed that creative individuals can successfully reconcile polar opposites, including masculinity and femininity, independence and dependence, serious and playful, conformity and nonconformity, timid and bold, certain and uncertain, and receptive and self-acting.

Csikszentmihalyi (1996) conducted interviews with highly successful individuals from various domains and careers. He stated that if there has to be only one word that differentiates creative personalities from others, it would be complexity. What Csikszentmihalyi implies by complexity is that personalities contain contradictory extremes. Although such complexity is basically present in each person, most people are trained to develop only one pole of the extremes. For example, they are trained to cultivate humbleness and repress their proud side. Creative people, on the other hand, can have both poles either at the same time or at different times, depending on the situation. This does not imply neutrality, which means that a creative personality is never very competitive or very proud. Rather, it implies the ability to move between two extremes, depending on the context. Csikszentmihalyi listed ten pairs of paradoxical traits, integrated with each other in a dialectical tension, among many the qualities that individuals hold.

1. Creative people have a great deal of physical energy, but they are often quiet and at rest. They can concentrate and work for long hours with enthusiasm. This is possible thanks to a superior physical aptitude. They have high energy even in their seventies and eighties. This does not mean that creative people are hyperactive; rather, they can rest and sleep a lot. The crucial point is that their energy is under control and targeted. They, on the other hand, often suffered from illnesses in their childhood. Creative people's energy is also paradoxically manifested in sexuality. They may have a quite strong dose of libidinal energy; however, they may accept celibacy as a part of their makeup.
2. Creative people tend to be smart yet naive at the same time. Research has established well that a certain point of IQ, usually suggested around 120, is required for creative work as well as superior performance in real life. However, any increment beyond that point does not necessarily facilitate creativity. The reason why low intelligence impedes creativity is understandable. However, it may be puzzling that high intelligence interferes with creativity. People with a high IQ may excessively rely on their knowledge or mental superiority; thereby, they lose their curiosity to create something new. They may not have an incentive to question, doubt, and improve on existing knowledge. As Goethe stated, "naïveté is the most important trait of genius." The smart-naïve paradox can also be defined as wisdom-childishness. People who attain childish novelty tend to use well two opposite ways of thinking: the divergent and the convergent.
3. Creative people combine playfulness and discipline, or responsibility and irresponsibility. They typically have playful attitude and its antithesis, a quality of endurance and perseverance. For instance, working hard for long periods of time is necessary to overcome obstacles and, for example, to complete a novel. At the same time, they need to be playful while spending long times on their work without getting bored.

4. Creative people alternate between imagination and fantasy at one end and a rooted sense of reality at the other. These are needed to escape from the present without losing touch with the past. According to Einstein, the two forms of break away from reality are art and science, because these go beyond what we consider real and create a new reality. A creative artist may be as much a realist as a physicist, and a creative physicist as imaginative as an artist.
5. Creative people tend to be both extroverted and introverted. These are considered as the most stable personality traits that differentiate people. Creative individuals, on the other hand, may have both traits at the same time. They are able to alternate between inner-directed reflection and intense social interaction. A creative person needs to be alone in order to focus on writing, painting or researching, while it is also important to see others exchange ideas and know their work and minds.
6. Creative people are humble and proud at the same time. Famous people are expected to be arrogant. However, they may be self-deprecating, shy, and humble because they are aware of their own contributions relative to others in the domain where they work. They are aware of the role of luck in their achievements. They are also focused on future projects and current challenges rather than past accomplishments. On the other hand, they know that they have accomplished a lot in comparison with others. Thanks to this awareness, they have a sense of security and pride, often expressed as self-assurance. This contradiction can be expressed as a contrast between ambition and selflessness or competition and cooperation. These people often need to be ambitious and aggressive to create; nevertheless, they are willing to subordinate their own personal comfort and advancement to the success of the project being worked on.
7. Creative people, to an extent, escape rigid gender role stereotyping. In all cultures, men are expected to be masculine and repress attitudes and behaviors that the culture considers as feminine, whereas women are reared to do the opposite. However, it has been found that creative boys are more sensitive and less aggressive than other boys, and creative girls are more dominant and tough than other girls. Psychological androgyny is a concept that refers to the ability to be simultaneously aggressive and nurturing, sensitive and rigid, dominant and submissive, regardless of gender. Creative individuals, thereby, have richer opportunities and the strengths of both genders. It should be noted that despite having cross-gender traits, in general, creative women are perfectly feminine and creative men are perfectly masculine.
8. Creative people are both rebellious and iconoclastic, and at the same time traditional and conservative. Creative people are expected to be rebellious and independent. Yet they must first internalize a domain of culture to be creative. The fact that creative people need to believe in such a domain and know its rules makes them to a certain extent traditionalist. However, they should be willing to take risks and break with the safety of tradition to change and improve.
9. Most creative people are very passionate about their work, yet they can be extremely objective about it as well. These two extremes are crucial, because passion enables creative individuals to attain their interest in a difficult task. Besides, being objective about work provides credibility and quality.
10. Creative people's openness and sensitivity often expose them to suffering and pain, yet also to a great deal of enjoyment. It is obvious that high sensitivity can lead to suffering and anxieties not usually felt by others. For example, a creative poet can suffer when reading a bad poem and an inventive engineer get hurt because of a badly designed machine. In addition, eminence invites attacks and criticism, which causes pain. Having an interest in ambiguous subjects and thinking divergently is often perceived as deviant by the majority and causes creative individuals to be misunderstood and isolated. Yet, it is true that when creative people are working in their area of expertise, they get rid of all of their worries and experience a great deal of enjoyment. They savor the process of creation for its own sake.

The conflicting traits abovementioned by Csikszentmihalyi may be the most striking characteristics of creative people. It is noteworthy that all of them may not be observed in the same person. Creative people know both extremes and experience them with equal intensity and without inner conflict. They can move from one pole to another on each continua of personality traits in order to integrate polarities and express what we call creativity.

Acar and Runco (2015) examined the role of contradictions in creative thinking, providing supportive findings to paradoxical creativity. Their hypothesis was to question the theory of divergent thinking by asserting that the existing divergent thinking tests do not measure actual or literal divergence. So, they developed a method to measure literally divergent thinking, which, in fact, diverge. Acar and Runco identified 13 conceptual dichotomies based on creativity theories and research. Their contradictory categories are indicated in Table 1.

They examined the ideas generated by a group of examinees and found that some people exhibited contradictory thinking. This capacity was also found to be correlated with an external measure of originality.

Paradoxes in Cognitive Thinking

Rothenberg (1996) stated that the creative thinking process involves Janusian thinking defined as the simultaneous conceptualization of two or more opposite or contradictory ideas, concepts or images. The term derives from the qualities of the Roman god, Janus, who had two faces that looked in diametrically opposite directions simultaneously. Rothenberg identified four levels of the Janusian process: (1) motivation to create; (2) deviation or separation; (3) simultaneous opposition or antithesis; (4) construction of theory, discovery, or experiment. In the creative thinking process, opposing ideas emerge at the second and third levels. Then, Janusian thinkers consciously conceptualize opposite or antithetical ideas, concepts or propositions as simultaneous coexisting. Although these conceptualizations seem illogical and self-contradictory, they are constructed logically and rationally to produce

Table 1 Conceptual dichotomies suggested by Acar and Runco

No	Polar 1		Polar 2
1	Originality	vs.	Conventionality
2	Amoral, unethical, illegal, and malevolent		Moral, ethical, legal, and benevolent
3	Taboo responses		Nontaboo responses
4	Primary processes		Secondary processes
5	Experience		Nonexperience
6	Functional and practical		Impractical, aesthetics, and artistic
7	Synthetic		Nonsynthetic
8	Breadth		Depth
9	Feasible, realistic, and possible responses		Infeasible, hypothetical, and unrealistic responses
10	Natural		Unnatural
11	Humorous		Serious and sober
12	Sober, playful, childlike, and spontaneous		Mature and responsible
13	Close		Remote

creative ideas. These contradictions often resolve and disappear at the fourth stage. According to Rothenberg, Janusian thinking is essentially secondary process thinking; however, it modifies the primary thinking process by providing its “seeming ubiquity” and allowing “primary-process-like material” to appear in consciousness. The Janusian process has an important role in scientific creativity. Janusian thinking occurs as early conceptions in the development of scientific theories and artworks, as well as at critical junctures at later stages. It is usually not apparent in the final creative product because it serves generative functions in the creative process, and its simultaneous antithesis or opposites usually undergo transformation and modification.

Living With Paradoxes

Each individual originally has many contradictory qualities and experiences paradoxes more or less throughout their lives. However, they vary with respect to their ways of responding to paradoxes. Beginning from the early years of life, the way a person deals with paradoxes contributes to his or her development of personality. Most individuals prefer to behave in accordance with one or the other antinomy when faced with a paradox. For instance, boys or girls are expected to behave according to their traditional gender roles: masculine or feminine. They know what is expected and usually behave accordingly. This is a kind of conformity to social norms or pressures from the outer world. Some individuals, on the other hand, may follow their true feelings rather than conforming. So, they can be both masculine and feminine, according to the situation. These individuals are more self-expressive, among other positive psychological traits. It has also well established that psychologically androgynous people tend to perform high in creativity. Thus, children should be encouraged to follow and express their authentic feelings, rather than follow what is expected and conform to the demands of others.

According to Runco (2016), when people face a paradox, they may use different options to responding to it (Table 2). The first is they may recognize that there is a paradox, but they decide not to think further on it. They consider it as a dead end and do not invest any more time. The second is an unrealistic option because some people ignore or deny the paradox despite the fact that there is one. If there is a paradox, it is a paradox and should be acknowledged. Closing your eyes does not mean everywhere is in dark. The third option is also unrealistic because some people emphasize one side of the paradox over the other. The paradox, thereby, is diminished and the situation becomes one-sided. The last option is to integrate or conflate the two polarities of the paradox into a new interpretation. As such, there is no longer a paradox, rather, a creative interpretation of it. This can be illustrated by

Table 2 Four ways of responding to a paradox

Options	Response
First	Recognizing the paradox, but deciding not to think further on it. Consider the paradox as a dead end and not investing any more time.
Second	Ignoring or denying the paradox despite the fact that there is a paradox.
Third	Emphasizing one side of the paradox over the other. The paradox, thereby, is diminished and the situation becomes one-sided.
Fourth	Integrating or conflating the two polarities of the paradox into a new interpretation. So, there is no longer a paradox, rather, a creative interpretation of it.

dialectic thinking. When you have a thesis, then an antithesis, and eventually reach a synthesis, this synthesis is literally a blend of the thesis and antithesis in a new interpretation. There is no longer a thesis or antithesis, only the synthesis remains. Among the four responding options, the last is the most difficult and creative. Those using the last option accept the paradox as a paradox rather than ignoring it. They acknowledge that the two extremes of the paradox are there and true despite the fact that they seem opposite. Although this option is difficult, it can lead to creative thinking.

Contradictions or paradoxes are not problems; rather, they are opportunities. Teachers and parents who want their students or children to fulfill their creative potential should first encourage them to deal with paradoxes. Parents and teachers can provide paradoxical situations to children so they can be aware and then learn to tolerate them. Thus, children may practice dealing with dualities and integrate them into a new interpretation. According to Kohlberg, children's cognitive and moral development can flourish by struggling with dilemmas. His approach is directly applicable to the current discussion because he emphasized the benefits of experiencing dilemmas.

Children should be taught the creative use of paradoxes. They need to learn how to tolerate paradoxes rather than avoid or deny them. They should interpret paradoxes rather than ignore or eliminate them. Thus, they can take control over the paradox and have the opportunity to practice creative thinking. An interpretation or reinterpretation of a paradox is the basis for personal creativity. So, educators and parents should model and support the personal creativity of their students and children by encouraging the creative interpretation of paradoxes.

Summary

Human beings originally possess multiple paradoxical characteristics. While have been weakened or fixed, creative people usually retain both poles of paradox, which results in the notion of a paradoxical personality.

Janusian thinking is defined as the simultaneous conceptualization of two or more opposite or contradictory ideas, concepts or images and is involved in the creative thinking process. Janusian thinkers consciously conceptualize opposite or antithetical ideas, concepts or propositions as simultaneously coexisting.

The research on paradoxical creativity is based mainly on case studies, currently showing scarce psychometric developments. Several researchers have specified paradoxical personality characteristics. For example, Csikszentmihalyi noted ten pairs of paradoxical traits based on interviews with highly successful individuals from various domains and careers. Acar and Runco identified 13 conceptual dichotomies based on creativity theories and research. In general, creative people know both extremes of paradox and experience them with equal intensity and without inner conflict.

From the early years of life, the way a person deals with paradox contributes to his or her development of personality. Most individuals usually prefer to behave in accordance with only one pole when facing a paradox. Indeed, contradictions or paradoxes are not problems; rather, they are opportunities. Therefore, children should be encouraged to follow and express their authentic feelings rather than follow what is expected and conform to the demands of others. They need to learn how to tolerate paradoxes and learn the creative use of them. Thus, they can take control over paradox and have an opportunity to practice creative thinking.

Gedankenexperiment: what would happen if Lev Vygotsky, Howard Gruber, Mihalyi Csikszentmihalyi, and Edwin Hutchins could work together with the task of coming up with a realistic and useful concept of creativity? In other words: what are the overlaps and synergies among sociocultural developmental theory (Moran and John-Steiner, 2003), holistic and constructivist lifespan development (Wallace and Gruber, 1989), sociocultural systems theory (Csikszentmihalyi, 1997) and research on distributed cognition (Hutchins, 1995)? Today, a number of emerging concepts of creativity combine these lines of research, including distributed creativity theory (Glăveanu, 2014a; Sawyer and DeZutter, 2009), some dynamic views of creativity (Beghetto and Corazzo, 2019) and recent elaborations on sociocultural views of creativity (Glăveanu et. al., 2019). Although all of these approaches describe the importance of social and/or material dynamics, certain theorists have focused on the different types of participation that bring about change in these systems.

Participatory creativity views thinking as largely constituted by social and material interactions over time – a distributed process – rather than solely or even primarily inside the heads of individuals. Although internal symbol manipulation certainly occurs as part of cognition and is important to creative work, the symbols come from the social and material worlds. Then the resulting ideas literally *take form* in the material world on computers and in notebooks, sketchbooks, lab journals, through conversations with colleagues, as well as in ultimate works. Much of the thinking of a painter is, thus, in the act of painting, of writers in writing and so on. Through this work over time, individuals develop distinctive points of view which they contribute back to their worlds in many roles. The painter, for example, draws from many people and sources in producing a work, and others – curators, gallery owners, collectors, reviewers, other painters, and so on – evaluate, interpret, reinterpret and respond over time. Indeed, the painter herself draws on multiple, internalized perspectives to produce the work. And all of the people in these roles are part of the creative process.

Theoretical Foundation

Drawing from the theories previously listed, participatory creativity builds on a number of foundational concepts.

- **Emergence in complex systems.** Creative ideas emerge through many people's work within complex, distributed social and material systems as described above. Even iconic "creative geniuses" drew from historical inspirations from books, paintings, and other artifacts, as well as from the contributions of teachers, colleagues, opponents, reviewers, and so on. People may be highly motivated to change social practices and material conditions, but they are never working outside of those conditions.
- **Creative work.** People who do creative work develop distinctive points of view over time through their participation in these systems as Gruber and his associates (Wallace and Gruber, 1989) argued. In other words, what develops through creative work is a point of view, as well as the ability to express that point of view effectively through a variety of possible roles. Indeed, it is common for people to participate in multiple roles. Writers are often also reviewers and editors. Scientists may edit journals and teach, and so on.
- **Integral roles of audiences.** In any of these roles people work within symbol systems that communicate ideas and, therefore inherently imply audiences. Those audiences may be institutional gatekeepers, such as editors and curators; formal audiences, such as collectors and consumers, or informal audiences, such as friends, and family. Audiences also include internalized representations of any of the above, a polyphony of learned perspectives, concerns, and values that people use to both inspire and evaluate the directions of their work.

- **Material actors.** Once thinking is liberated from the head, occurring within work not just in often fleeting internal symbol manipulations, the world itself becomes part of creative processes. Artifacts are actors. The artifacts do not themselves have intention but they are crucial in conveying, invoking, inspiring and influencing intention. A chance encounter with a work of art or literary passage can lead to whole new directions of creative work. Furthermore, the material world pushes back. Paint once on the canvass does not necessarily conform to the artist's vision or ecosystems to the vision of economic innovations. Such "problems" often guide the direction of work.

Taken together, these concepts shift some of the usual definitions in creativity research as well as the core questions that research addresses.

Definitions

- **Creative work.** Borrowing again from the developmental theory of Gruber et al., here creative work is the organization of resources to develop and express new and valuable points of view through a variety of possible roles.
- **Creativity.** The emergent course of change that results from these contributions determines what may be considered creative. In keeping with the long list of scholars who have argued that creativity is a value judgment (e.g., Amabile et al., 1996; Csikszentmihalyi, 1997; Glăveanu, 2014a), the creativity of any particular course of change – its value – must be an ongoing debate.
- **Creator as producer.** Note that in this approach people are not creative. They are not labeled as more or less creative or tested for their creativity. Traits like divergent thinking, along with the skills and knowledge people acquire, are resources that people can exploit and must manage to do creative work. What then happens to the individual creator? Were the works of the likes of Einstein, Picasso, Coltrane, Kahlo, and Gandhi not extraordinary? Such efforts remain extraordinary and important, but the individuals are not seen as solitary generators of the ideas for which they have come to be known. They are described as crucial *producers* who take leading roles in the exploration, construction, and advancement of particular points of view (including style, techniques and so on). In participatory creativity there is less pressure on these people to "be" extraordinary at every turn or to think "outside the box" of knowledge and experience than in more individualistic views of creativity. At the same time the participatory approach provides a realistic framework for understanding the goals, challenges, and possibilities of the producers' work.
- **Biographies of ideas.** History is also key for those doing creative work in any role and at whatever scale. Both everyday and earth-shaking ideas have "biographies" to which many people have contributed, not just those often credited with the idea. Understanding that can be important to the person who wants to influence the current course of history as creative producer or as part of the field evaluating works. It is also, of course, important for the student learning history. Then within any classroom project, the students' awareness of the biography of their ideas – the sources of inspiration, the wandering course of idea development, the number of contributors, and the roles they have taken on – can help position their ideas within the subjects they are studying, as well as promote collaboration and self-awareness. This awareness may also facilitate greater appreciation of peers and help the students define their goals for future participation within a realistic view of how creative change occurs.

Note: there is no claim that creativity is inherently or objectively good. The definition of creativity as producing a new idea or product that is of value still stands, but the relative nature of value is acknowledged. One person's art is another's sacrilege, one's exciting economic "disruption," another's economic ruin. The complex dynamics of creativity as a value judgment may be local, transitory and limited as in teachers and students recognizing new ideas in the classroom or viral videos on the Internet. The judgements can also be long-term and institutional as in recognized masterpieces in art and advances in science. In any case, though, "fields" can be nurturing as the agrarian metaphor suggests, as well as battlefields of value and change.

Even more inherent to the participatory approach than relative nature of value is the unpredictable nature of complex systems. By definition complex systems are not precisely predictable. Unexpected outcomes are not just possible but characteristic of the system dynamics, making the creative work of the "field" an ongoing process. Again, that work – idea evaluation, integration and application – involves both conflict and consensus among many people in a variety of roles.

New Questions

From individuals', organizations' and research perspectives, then, this view expands the questions about creativity. "How can I think of a new idea?" or "How do we help others think of new ideas?" are still relevant but no longer alone or even central. The more important questions become "What change do I want and how shall I participate – what roles shall I take up – in bringing change about?" Then: "How do I obtain and organize the knowledge, skills and gain access to the necessary social and material resources to be effective in those roles?" And: "How should each particular group or society set up its practices and institutions to help people make meaningful contributions?"

In addition, the crucial roles of idea evaluation, elaboration, and integration become important topics of research. How do the dynamics of different fields differ? How has technology changed roles? How can different combinations of roles serve the needs of different kinds of people and different historical conditions? And so on. There is also an overarching ethical controversy here.

Csikszentmihalyi (1997) stated the challenge, citing a quote from Jonas Salk about the goal of becoming “good ancestors” (p. 325) amid all of the complexity, unpredictability and debates, described above.

Goals

If there are other theories of distributed creativity, why define one that focuses specifically on issues of participation? Like other distributed and dynamic theories, participatory creativity aims to synthesize and advance current theoretical frameworks. Beyond overall systems analysis, the participatory lens then focuses specifically on how individuals experience, and contribute to, distributed creative processes. These are questions of development, education and roles within complex systems. This participatory focus is meant to enhance relevance to everyday and work life and to increase appreciation of creative contributions from different roles. The hope is that this appreciation will motivate greater participation by people who do not see themselves as visionaries or have been historically excluded from creativity narratives.

Advancing the Theoretical Framework

Each of the theories on which participatory creativity and related theories are built – developmental theories, sociocultural systems perspectives, and distributed cognition – overlap, each focusing on different aspects of creative agency and change, while including consideration of the core interests of the others. In the kind of distributed, historical process participatory creativity itself describes, these theories have contributed to different parts of a larger picture. The resulting, overall synthesis is hard to miss. The participatory questions concerning roles and patterns of participation for individuals can be overlooked, however. Indeed, focus on big-picture systems analysis can easily lead researchers *away* from individuals’ perspectives, challenges and development as participants in these systems.

Responding to the Needs of Everyday Life

Although the participatory view applies to creative work across history, today’s networked technologies have made the distributed nature of idea generation and evaluation part of everyday life. From online workplace collaborations to Wikipedia to viral memes to multiuser online games to social-network driven revolutions, the creative power of distributed systems is obvious. And the stakes are high. As noted above, the value judgment of creativity is a battlefield. Complex distributed systems currently build and promote exciting ideas to make life easier, healthier and more entertaining. Such systems also magnify bullying, produce “fake news,” and destabilize democratic institutions. Knowing how to think about, participate in, and manage these systems is emerging as one of the most important challenges of the 21st century.

Focusing on Practical Applications

As a conceptual framework participatory creativity applies to any of the contexts where creativity has been a concern. For example, Glăveanu (2014a) has studied how Romanian egg painters work within distributed systems. The technology startups that have grown rapidly in recent decades already understand complex distributed systems at the core of many of their products. Participatory creativity is then a translation of the products of this business sector to corporate organization and practices and to the development of the companies’ employees and founders.

To date, however, the main focus of participatory creativity theorists has been education. Hanchett Hanson has argued that teaching complex systems theories and practice is among the most important tasks for education in general and participatory creativity in particular. Traditional subjects can help students understand how new ideas emerge and are applied these dynamics. For example: historical research on the integration and unexpected consequences of new discoveries. In addition, study of biographies of traditionally recognized “geniuses” within the participatory framework can be a powerful means of deconstructing individualist mythologies and understanding the challenges and opportunities involved in creative work.

Clapp has worked with traditional classrooms and with design and makerspaces, emphasizing use of “biographies of ideas,” discussed earlier. In students’ projects both the values of multiple roles and the emergent nature of ideas can become evident when students and their teachers track the biography of their ideas. The same principle applies to studying history. At one school a teacher who traditionally taught a unit on Henry Ford as the man who brought the assembly line to mass production, now teaches the longer history of mass production in which Ford’s contribution is one component. The teacher sees advantages to acknowledging the contributions of many people over time, instead of focusing on the ideas of one man who had little in common with her students. In this approach she hopes to teach history more accurately and inspire students to see themselves as prospective participants in creative processes.

Clapp has also studied participatory profiles of students – a tracking of the frequency and amount of time different members of a student team spend in different roles (e.g., researcher, technician, spokesperson). This tool can help educators see the dynamic ways that students participate in creativity and can help students understand their own engagement in ways that honor their diverse talents, skills, background experiences, and perspectives. Clapp has emphasized, however, that the participatory profile should not be seen as a personality typology, closing off opportunities to take on new roles. In addition, there is not one set of defined roles that

fits every kind of creative work. On one project researcher and technician might be key roles, and another project might have roles for paint mixer and stylist.

Perhaps the most powerful educational impact participatory creativity can have is its emphasis on everyone's capacity to participate in creativity. Using the participatory approach, educators can proactively invite, honor and sustain diverse social and cultural perspectives, moving beyond emphasis on a select few – usually white men – that are used to illustrate creativity in many individual-based approaches.

Research Methods

Approaches to creativity that emphasize emergence in complex, distributed systems – including the participatory approach – have used a range of methodologies. There is still, however, much work to do. A crucial challenge to research is that the participatory approach is conceptually more comprehensive than any methodology will be. Therefore, it serves as a framework for designing and understanding research that will necessarily be more focused. At the same time, to be consistent with this framework research must avoid being reductive. In practice, this balance has generally been accomplished by studying several, but certainly not all possible, components of the systems in which people do creative work.

In-depth case studies of creative work have both inspired and facilitated development of participatory principles because this method is designed to study systemic interactions at a detailed level, rather than isolated variables. In applied settings, mixed methods have been used to capture multiple aspects of creative work dynamics. For example, in a study of a youth development program, Hanchett Hanson used a pre-/post-test design on social interaction tendencies with a test and comparison group. Those findings triangulated to observational rubrics and coded interviews to understand impacts of the social, material and temporal distribution of trauma narratives.

In general, participatory creativity studies have included observational rubrics, interviews, and a variety of different types of interaction analysis. An example is Clapp's use of the participatory profile and development of a biography of the students' ideas, previously discussed. In a different type of interaction analysis Glăveanu has used subjective evidence-based ethnography to study the interactions of a painter with his medium. The painter wore glasses equipped with a camera to capture his point of view while working then reviewed the video with the researcher.

Finally, the participatory approach provides a framework for re-evaluating other existing lines of research, such as trait theories, motivation research and historiometric research.

Conclusion

Participatory creativity is one of several related and recently emerging systems approaches to the concept and research of creativity. As the name suggests, participatory creativity reframes creative work as participation in a wide variety of possible roles within complex distributed social and material systems over time. This approach, thus, stands in opposition to the individualism that has characterized much of the history of creativity research as well as reductionist views of creativity as dependent on a single trait, trait profile, or formulaic process. Participatory creativity advocates a stance toward creativity that invites the widest breadth of perspectives into the creative process – including the perspectives of diverse groups of people who are often excluded from the popular creativity narrative.

For individuals, organizations and researchers, the participatory approach expands the core questions of creativity. Questions of ideation remain relevant, but now the more central questions concern what changes people desire in their worlds, in what roles they can help effect those changes, and how to develop meaningful points of view on those changes. That development includes acquisition of knowledge and skills and access to social and material systems. These questions also come with ethical considerations. For, amid the complexity and unpredictability, creative participation is inevitably participation in the ongoing debates about what changes are needed, what they mean and how they should be applied.

Intellectual property is an umbrella term that refers to any product of human creation. To protect intellectual property, a variety of methods have been developed, such as patents, trademarks, service marks, and copyrights. Artistic works, ideas, and the discovery of rules are not patentable. They are, however, protected under copyright laws. The present chapter focuses on patents, defined as *"the grant of property right to an inventor."* For the patentee, patents provide the right to exclude others using, making, selling, or importing their inventions. Patent systems have two main purposes: to encourage the development and disclosure of new creative works and inventions. First and foremost, patent systems aim to reward and encourage inventors for their research and creative work. Second, patents help to publicize scientific and technical ideas, which allows others to learn and reproduce an invention.

Although the issues of patents, trademarks, servicemarks, and copyright are hot topics in the modern economy, ideas and inventions have been the subject of intellectual property for a long time. While there is some historical evidence indicating that the initial version of patent rights first arose in Ancient Greece, Venice, an Italian state, is considered having the first patent system offering exclusive rights for inventions and new technologies in 1474. Gradually, many other European countries adopted similar patent systems from the Venetians. The goal was to improve economic development and protect intellectual property, but patent systems were also exploited for political and financial benefit.

In England in 1623, the Statute of Monopolies transferred the power to grant patent applications from the king to the parliament, which provided the foundation for modern patent laws. In colonial America, the first patent was granted by the Massachusetts General Court to Samuel Winslow for his invention of a new method of salt production. In 1790, the United States Patent Office was founded through the instruction addressed in the US Constitution that states *"Congress shall have the power ... to promote the progress of science and useful arts by securing for limited times to authors and inventors the exclusive right to their respective writings and discoveries."* In the same year, the first US patent was issued for Samuel Hopkins who invented a process of making potash, an ingredient used in fertilizer. Today, patents are the core of the global economy and competition with over three billion patent applications and hundreds of thousands of granted patents in each year around the world.

How the Patent Process Works

Different national and international patent institutions are recognized as having authority over patent-applied inventions and products. Many countries have their own governmental institutions, which take care of local patent applications. Since applying for patents in many countries is not always viable for inventors, some international organizations, such as the African Regional Intellectual Property Organization (ARIPO), the European Patent Office (EPO), and the World Intellectual Property Organization (WIPO) provide international patent rights for patentees. In the United States, the US Patent and Trademark Office (USPTO) is the main agency that processes patent applications for inventors and businesses.

The USPTO permits the granting of three types of patents: utility, design, and plant. Utility patents are for a new and useful process, machine, article of manufacture, or composition of matter, or any kind of innovation and improvement for listed categories. Inventors who develop a novel design for an article of manufacture can obtain patents for designs. Lastly, the invention, discovery, and asexual reproduction of a distinct and new kind of plant is patentable. Once an application is submitted, it is evaluated by examiners to see if the claimed invention is new, useful, and nonobvious, and whether the application complies with the

[☆] Change History: August 2019, Paula Thomson updated the text throughout the article.

This article is an update of P. Thomson, M. Godin, Acting, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 1–8.

legal requirements. The evaluation entails an intensive review of national and international patent documents, patent applications, and available literature regarding the claimed invention. When a patent is granted, it gives a legal monopoly to the patent holder for the following 20 years, starting from the date of application. Like any other property, it can be used for commercial purpose, as a gift, or left in a will.

US Patent and Trademark Office's Criteria for Creativity and Definition of Creativity

Defining creativity for both research and practical purposes is important because the definition influences the way we understand, measure, and research the phenomenon. Unfortunately, there is no consensus among researchers about the definition of creativity, but originality and usefulness are two terms that have been commonly used to define it. Runco and Jaeger noted that the original definition of creativity goes back to before 1900s, but they argued that Morris Stein should be credited for the standard definition of creativity as used in his paper in 1953. Since then, originality and usefulness have been used in creativity research as common defining terms.

Originality has been widely accepted as a defining characteristic of creativity, referring to novelty, uniqueness, and being uncommon. Novelty occurs in highly original things done by animals or found in nature and some ideas from people with mental illness, but such novelty does not make them creative. Therefore, it is not surprising that originality itself is not enough to define creativity. Creative products should also be intentional, and any novel products or ideas should be useful and serve a specific purpose.

For this second criterion, a variety of terms are used, such as usefulness, effectiveness, having value, appropriateness, or fit. For instance, The Systems Model of Creativity by Csikszentmihalyi (2014) suggests that a product be labeled as creative through a cyclic process. When an individual brings novelty into a domain, it is recognized and validated by experts and gatekeepers in the field. Gatekeepers make judgments not only about novelty, but also about the value of a product. Usefulness or appropriateness are more concerned with whether a product is feasible or effective for a given problem. For evaluation purposes, usually a dichotomous rating is used to determine if a given response is useful or appropriate for a specific problem. Considering the alternative uses (AU) divergent thinking test, the response "use as a saucepan" for alternative uses of "a cardboard box" may sound highly original, but it is neither useful nor appropriate, and thus would be considered a non or less creative response.

The US Patent and Trademark Office uses a similar but extended set of criteria in their examination of patent applications. Instead of two, they use three criteria: novelty, usefulness, and nonobviousness. For novelty, the USPTO requires that an invention not be "*patented, described in a printed publication, or in public use, on sale, or otherwise available to the public before the effective filing date of the claimed invention.*" Usefulness suggests that an invention has a practical utility. Lastly, regarding nonobviousness, a patent may not be accepted "*if the differences between the claimed invention and the prior art are such that the claimed invention as a whole would have been obvious before the effective filing date of the claimed invention to a person having ordinary skill in the art to which the claimed invention pertains.*"

Thus, the first two criteria are commonly known in creativity literature, but the USPTO requires a new one, nonobviousness. As Dean Keith Simonton suggested, it could be considered or renamed as surprise. Surprise as a criterion of creativity is not new for the creativity literature; it was discussed by early researchers. Jerome Bruner, for example, addressed how creativity requires "effective surprise", and Margaret Boden used surprise as the third criterion of creativity along with novelty and being valuable.

Amy Landers (2010) elaborated on nonobviousness, "a person of ordinary skill," and the creativity-patent connection through an extensive review of the literature and court cases about patent applications. She pointed out that a person with ordinary skills is considered to be someone who has domain-specific knowledge and can apply it mechanistically. If a claimed invention can be re-created by a person of ordinary skill, it implies that the claimed invention is a predictable variation of the state of the art; thus, it doesn't fall into the category of nonobvious, and any patent application for such a claimed invention should be rejected. For instance, nails are widely used in the furniture industry, but using glue instead of a nail for a table or chair is a predictable variation of furniture manufacturing, and thus should not be rewarded with a patent. Interlocking wood sections that do not require nail or glue, on the other hand, could be considered for a patent application as a nonobvious improvement.

Based on the patent guidelines of the US Patent and Trademark Office, Simonton (2012) proposed a new definition of creativity that extends the current two-criteria approach by adding surprise as a third criterion. He used the formula, $C = N \times U \times S$, where N, U, and S stand for novelty, utility, and surprise, respectively, to show how the new definition might change current assessment practices. From this perspective, a product or idea is considered as creative when all three criteria are met, or mathematically when $C = 1$. The lack of any criterion leads to a non-creative result, such as when a product is novel and surprising but has no utility, it becomes non-creative ($C = 1 \times 0 \times 1 = 0$). Simonton pointed out that the new three-criterion definition with a multiplicative assessment approach has four implications for the assessment of creativity and creativity research.

The first implication is that the person of ordinary skill addressed in the definition of nonobviousness suggests that surprise is determined by a domain-specific expertise. When a claimed invention is seen as obvious by a person of ordinary skill, the invention will have zero surprise, and thus is considered non-creative. Although domain-specific knowledge might be necessary for creativity, it is highly questionable that surprising and creative products emerging from the combination of irrelevant or remotely associated ideas can be determined by expertise. Secondly, the three-criterion definition allows for a more flexible and culturally-sensitive assessment of creativity. While a dichotomous scoring, creative (1) or non-creative (0), is still a valid way to determine creativity,

with a three-criterion definition, scores can be weighted based on social context or the culture, and ideas or products can receive partial credit in assessment, such as 0.5 for novelty or 0.4 for surprise. Thirdly, surprise as a defining characteristic brings a new perspective to the subjective and objective conception of creativity. While the criteria for patents are explained and assessed objectively, the subjective assessment of surprise may widely change depending on an inventor's personal experience. Lastly, Simonton suggests that the three-criterion definition makes blind-variation and selective-retention (BVSR) a required process that separates creative ideas from non-creative ones through the generating and then testing procedure.

Although the three-criterion definition is not new for creativity researchers, further discussions on the operational definition and assessment of creativity based on the US Patent Office's criteria might open new possibilities and contribute to the understanding, practice, and research of the subject. Critiques of the three-criterion definition, on the other hand, may help to change and improve the current patent systems and evaluation processes.

Do Patents Foster Creativity?

Patent laws provide property rights as an incentive to inventors and researchers, and it is assumed that such incentives increase the quantity and quality of creative production. Patent laws may encourage inventors to invest their time, energy, and resources to pursue their work and creation. Otherwise, many inventors would not make an effort to create an invention in an environment where intellectual properties are easily copied and used freely by others. Patent laws are apparently effective motivators for inventors; however, it is controversial whether extrinsic motivation and rewards facilitate creative production. Teresa Amabile, for instance, proposed the componential theory of creativity, suggesting that creativity requires expertise, creative personality, and intrinsic motivation. In point of fact, extrinsic motivation and rewards have been frequently cited as the factors that reduce creativity. It is not surprising that doing something for personal interest, enjoyment, satisfaction, and fulfilment is associated with creative personality and production. Extrinsic motivators, however, are inevitable in many cases in which anticipated rewards and recognition are likely to contribute to the creativity of outstanding scientists and artists. For instance, James Watson, a well-known biologist and Nobel prize winner, had both an intrinsic and extrinsic motivation to win the Nobel prize as documented in his autobiography. As expected, personal recognition is the driving force for many creators. Thus, extrinsic motivation may not be as detrimental as previously considered if rewards and other extrinsic motivators are used as contributing factors rather than the main motivation of creative production.

Regarding the specific role of the patent system, there are two opposing views about the motivational function of patents on creators. One approach supports the idea that rewarding researchers and inventors with a patent might be counterproductive or even undermining for creative efforts. Theoretically, inventors are expected to have passion and an intrinsic motivation for their work; thus, they do not need an extrinsic motivator. An opposite view suggests that patent laws actually provide autonomy and foster intrinsic motivation, which in turn improves creative production. Of course, not all patents function as direct prizes for patentees. Unlike common rewards or grants in many domains, patents just provide exclusive rights, which may turn into greater benefits in the long run for inventors and businesses. Patents that lead to commercialized products may lead to greater returns for inventors; hence, there is an increasing number of patents and innovations in commercialized industries. It is also a reality that there are many patented inventions that are worthless based on the current economy of modern life, but many people continue to work on inventions that will not bring any economic benefit for the patentee [Nicholas \(2013\)](#).

Michele [Boldrin and David Levine \(2013\)](#) argued that there is a lack of evidence that patent systems improve innovation and productivity, unless productivity is not considered an equivalent to the number of granted patents. They pointed out that the number of patents has no correlation with productivity. The correlation between the patent system and innovation and productivity is controversial, and it is not surprising that the correlation differs based on the definition and measurement of innovation and productivity. Michele Boldrin and David Levine still have many valid points as to why patent systems may undermine creative production. For instance, while patents are effective incentives for inventors, they negatively impact the ability of every other researcher in the field to compete with the patent holder. Past patents also inhibit current efforts for further innovations, because the new innovators need to overcome many legal challenges and licensing requirements by patent holders.

A great case from history is the Wright brothers. Although there were several inventors in the aviation field, the Wright brothers have been credited as the inventors of the airplane because of their success in the first airplane flight and the patent for their flight control method. While their invention was a great success for the aviation industry, their airplane needed improvements to be a sustainable and reliable alternative for transportation. Instead of continuing their effort to develop a better airplane, the Wright brothers spent the rest of their career controlling the aviation industry and suing local and international aviators for infringements of their patent rights. Because of their excessive focus on patent protection, they were called "patent trolls" by Sean Trainor in *Time* magazine. Their contemporary and biggest competitor, Glenn Curtiss, however, spent most of his energy and effort creating a more viable airplane vehicle instead of being concerned about patenting his contributions, thus leading to many great inventions in the aviation industry. The Wright brothers, of course, filed many lawsuits against Glenn Curtiss and eventually required him to pay licensing fees for their patent. Their excessive control of the aviation industry stifled further innovation and progress in the aviation industry until the US government stepped in to solve the problem after World War I.

A similar story is the case of Thomas Edison. As [Adam Jaffe and Josh Lerner \(2011\)](#) mentioned in their book, *Innovation and Its Discontents*, Edison was granted the patent for lighting in 1880. During the following decade, a dispute arose about restrictions in the lighting industry due to Edison's patent rights. In 1891, Edison's company, Edison General Electric, filed lawsuits against its competitors. As with the Wright Brothers in the aviation industry, there was a dramatic slowdown in lighting industry regarding new

improvements and inventions. It continued until the patent expired. To be fair, it should be noted that Edison and his team conducted over a thousand experiments and spent a lot of money, time, energy, and resources to invent the first successful light bulbs and receive the patent rights. Thus, his desire to interpret the patent rights in an extended way and restrict other companies to use and improve his invention for commercial purpose is understandable. Nevertheless, the patent for lighting in this case undermined subsequent efforts to improve and develop more effective and sustainable lighting instead of encouraging inventors to work on lighting projects.

This blocking effect is more obvious in the current global economy in which the production of many goods consists of many smaller components, all of which are subject to patent laws. For instance, a mobile phone has a screen, battery, charging technology, technical solutions, camera, operating system, and transmitter, such that a new inventor or company has to deal with the patent holders and the long-licensing procedure to be able to produce and sell their products. Many big companies, like Apple and Samsung, spend billions on patent wars, which leads to a reduction in their budget for research and development. Since Steve Jobs introduced the iPhone and Mac computer, there has not been an extraordinary invention in the computer and phone industry beyond making products lighter and thinner.

It is also not surprising that many great historical inventions, even in 19th and 20th centuries, emerged outside the patent system. Thus, the patent system may not be the underlying mechanism contributing to creativity and innovation. As Michele Boldrin and David Levine suggested, inventors may receive similar benefits from their inventions through different mechanisms, such as first mover advantages. Summing up, despite the addressed benefits for patent holders and providing incentives for researchers and inventors, the current patent system seems to be detrimental to creative production.

Multiple Discovery and Patents

Multiple discoveries, also called simultaneities, occur when researchers work on the same project or invention in a parallel but independent way in the same time period, and the same or highly similar invention is created by two different inventors. One of the most famous examples of multiple discovery is calculus. In 18th century, both Isaac Newton and Gottfried Leibniz discovered calculus simultaneously. Although Leibniz was the first to publish an official paper about the topic in 1684, Newton made some references about calculus in his personal notebook as early as 1666. In the aviation industry, Jean-Francois Pilatre de Rozier succeeded the first balloon flight in 1783. Although the Wright brothers are known as the fathers of the airplane, a couple of other inventors, such as George Cayley from England, Gustave Whitehead from Germany, and Richard Pearse from New Zealand achieved their own flights all before the Wright brothers. The Wright brothers received the credit because of their invention of the controlling mechanism, the first “successful” flight, and being granted a patent for their invention. Furthermore, identical theories of natural selection were developed by Charles Darwin and Arthur Russel Wallace independently.

Multiple discovery is not limited to these famous inventions and discoveries; indeed, it is a common pattern seen in science history. In an early study, William Ogburn and Dorothy Thomas cited 148 multiple discoveries in 1922. Dean Keith Simonton used 579 multiple discoveries for the analysis in his seminal study about multiple discovery and invention, and it is possible to add many more since then. Ogburn and Thomas believed that innovations become inevitable considering that accumulated knowledge and social development encourage inventors to invest their attention and resources in a particular problem. Their approach seems to contradict the “great man” or “genius” theory that attributes discoveries and progress to exceptionally talented individuals (See Discovery and Multiple Discovery).

It is not surprising that required knowledge and ideas had been available for a long time for some inventions before they were finally brought into being. For instance, even though flying cars have been a dream for a long time by many people, and the technology in the aviation and car industries has been available to combine two different transportation technologies, a patent application for a commercial flying car was just filed in 2018. Thus, with accumulated knowledge and social demand, people with exceptional creative and intellectual abilities still play an important role in inventions.

The *zeitgeist* is also a useful phenomenon to understand multiple discoveries. As defined by Edwin G. Boring in his seminal paper in 1971, the *zeitgeist*, a German term meaning the “spirit of the times,” refers to “the climate of opinion as it affects thinking” and “the total body of knowledge and opinion available at any time to a person living within a given culture.” The *zeitgeist* favors certain domains or inventions at certain time periods. In the Renaissance, for example, art, literature, and philosophy were highly appreciated, which may explain why some of the greatest scientist, inventors, artists, or authors emerged during this period. Leonardo da Vinci, Michelangelo, and Sandro Botticelli are just some of the Renaissance artists who have had a lasting influence on modern art (See *Zeitgeist*).

Besides the concepts of genius and the *zeitgeist*, Simonton (1979) also examined chance as a theory of multiple discovery. He conducted four critical tests to determine which theory is most plausible to explain the multiple discovery phenomenon. The results indicated that chance theory was the best explanation. Although chance theory was the most significant one, Simonton pointed out that genius and *zeitgeist* theories are still valid approaches to understand multiples.

While Simonton’s study included an extended list of multiple discoveries, national or international patent offices are in a better position having a potentially vast amount of data and information about multiple discoveries. These patent offices have the authority to grant patents in cases of multiple applications filed by independent inventors for the same or similar inventions. In the last decade, more than half of the patent applications have been denied each year, and it was also the case in the earlier decades.

Although a lack of usefulness and nonobviousness might be the reasons, a lack of novelty is possibly the most common cause for rejection. Adam Jaffe and Josh Lerner (2011) addressed how the US Patent Office's handling of the issue of novelty for multiple discoveries may undermine the development of subsequent improvements. It is common for different companies or individuals to apply for a patent for the same or a very similar idea or set of ideas. It might be fair that they all receive credit for the unique aspect of their creation, but in reality, it is not the case most of the time. Patentees usually use a considerably ambiguous language for the description of their inventions, which may lead to different interpretations about whether the current patent covers similar improvements or inventions by other applicants. It makes the patent system a subject for courts and some judges favor a narrower interpretation of patent coverage, while others favor a broader coverage of patent rights and the interpretation of a description of an invention. As a result, many companies or inventors hesitate to commercialize their ideas due to the possibility that they might encounter the extensive cost of a lengthy litigation process.

Patent systems are expected to improve innovation, however, patent systems in such cases may undermine rather than improve innovation. A great example from history is the invention of the radio by Guglielmo Marconi (Of course, who invented the radio or many other inventions is still a controversy for some.) Besides the radio, he was granted a patent on the two-element vacuum tube, called a diode, which was used in radios and TVs. Lee De Forest, an American inventor, improved the diode and invented the triode. Although the triode was a distinct and improved model of the diode, the case became the subject of litigation. The court ruled that the triode was an improved version of the diode, and Lee De Forest and AT&T, the owner of the triode patent, needed to receive a license from Marconi to be able to use it. Marconi refused to offer a license, and the use of the triode, a major improvement in technology, was delayed due to the dispute. Because of similar problems, Kent Walker, Google's Senior Vice President for Global Affairs and Chief Legal Officer, once said in an interview that "A patent isn't innovation. It's the right to block someone else from innovating."

Patents in Assessment of Creativity

The assessment of creativity is a fundamental issue in creativity research. Since Guilford's seminal speech at the 1950 APA Annual Convention, a variety of measurements of creativity has been developed. Available assessment methods in the creativity literature aim to measure various aspects of creativity, including but not limited to, divergent thinking, creative personality, creative achievement or activities, personal attitudes, and product evaluation. One distinction among creativity tests is the use of subjective vs. objective assessments. A subjective assessment usually relies on self-report data, personal observation, and the perception of supervisors, teachers, parents, or raters, which might be biased. An objective assessment, on the other hand, requires expert judges, trained raters, or computer programs for scoring creativity tests.

Although divergent thinking tests rely on individual performance on given divergent thinking tasks, many creativity studies base their findings on self-reported data about different aspects of creativity, such as ideational behavior, creative achievement, personal attitudes toward creativity, and the perception of support for creativity in school or work settings. In many cases, the validity of self-reported data is questionable unless the findings are triangulated with other measures and evidences included in the study.

For instance, there is a growing body of research about the perception of teachers on creativity and creative students. The results, in general, imply that teachers value creative children and creativity as an essential skill for the 21st century. When it comes to classroom practices, however, many teachers find it highly challenging to deal with creative students or integrate creativity in their regular curriculum. Thus, teaching practices might not be in line with teachers' self-reported beliefs and values about creative students. As an alternative, researchers use observations, self-report data from teachers, students, and parents in schools, or employees, co-workers, as well as supervisors in organizational settings to triangulate the data sources, whereas these supporting data sources are still not free from bias and could be influenced by demographic characteristics, social desirability, personal relations, and the halo effect (See Education).

Patents and patent applications are considered relatively more objective ways to assess creativity and are used as criteria for creativity and innovation in some studies. The number of patents or patent disclosures written by individuals has been used to assess personal and group creativity. From a broader perspective, these patents are used to compare regions, states, or even countries regarding how creativity and social and political structure are connected, as well as how productivity and innovation differ around the world. As stated, patent applications are reviewed by expert examiners, and for nonobviousness, "a person of ordinary skill" plays a key role in determining whether a patent application is a predictable variation of an available product or invention. Both examiners and "a person with ordinary skill" rely on their expertise to judge whether a patent application meets the required criteria. Using one's expertise for the assessment of creativity is not something new in the creativity literature. Teresa Amabile, for example, developed the Consensual Assessment Technique (CAT) in which participants are asked to create a creative product, which are evaluated by a group of experts in that field. A number of studies using the CAT has revealed considerable evidence of inter-rater reliability (See Consensual Assessment) Patent evaluation is, of course, not identical to the CAT, but it still relies on personal expertise. With a limitation of expertise on assessment of surprise or, in general, creativity as a complex phenomenon, patent applications or the number of patents could be considered as an alternative and more objective way of assessing creativity, especially in the research and development industries that require a high level of innovation.

Patents in Creativity Research

As mentioned above, patents have been used in creativity research literature as an indicator of creativity. For instance, Huber (1998a, 1998b, 2000) examined big C creativity among inventors and used the number of patents, as a form of nationally recognized achievement, to measure creativity of the inventors. His studies indicated that inventorship is a form of creativity, patented inventions are rare, and the time pattern of inventions is random. McCann (2011) also used the number of patents per state to examine the relation between creativity, conservatism, and openness to creativity. Based on the results, the number of patents per state population was lower in conservative states and higher in more open states. McCann's study was extended and replicated by Runco et al. (2017). The number of patent was again the criterion measure, but instead of state level, it was used for counties. The results supported the negative correlation between conservatism and creativity.

From a different perspective, Huang et al. (2012) examined global collaborative creativity based on the number of patents emerged through international collaboration. Their study indicated that there is a growing number collaborative work among international researchers, and more and more patents are granted through collaborative creativity. Instead of number of granted patents, patent applications or disclosures were also used to measure employee creativity in organizational settings (Oldham and Cummings, 1996). Clearly, use of patents in creativity research is not limited to the cited studies, and patents, patent applications, and the creativity framework suggested by US Patent Office continue to offer useful research tools and questions for creativity researchers.

Conclusion

Patents entail legal documentation to protect the products of intellectual property and provide exclusive rights for patent holders for a specific time frame. It has a long history and currently there is an increasing interest and global competition in patent applications and protecting intellectual property rights. The patent systems are highly influential to creativity, especially in domains with high number of commercial products, and have implications for research, development, and the understanding of creativity. For patentees, patents provide exclusive rights and benefits, and they function as an effective incentive for investor's commitment in time, money, and resources. For many firms or individual researchers, however, the patent system is a burden that discourages new firms and researchers from improving and commercializing patented inventions due to the fear of legal challenges and licensing requests by patent holders. Another critical issue concerns multiple discoveries and the tendency for patent systems to favor the initial and more salient applications, which leads to undesirable results for the other applicants, even if they had the same idea or invented the same or a very similar invention during the same time frame or even before. It is highly questionable whether the idea of a patent or patent system still serve the purpose in encouraging the development of new creative work. Further studies and discussions are needed to improve the current patent system and establish well-defined boundaries for patent monopolies.

Glossary

Discretion Knowing when to be creative and when to be conventional instead.

Intentions Usually a reflection of a value system and may lead to mindful efforts and are thus often apparent in what the person is motivated to do.

Interpretation The result of cognitive processes, and in particular those involved in the construction of meaning.

Personal creativity Original and effective thinking and behavior that may have no social expression and may not lead to manifest product.

Self actualization The highest form of psychological health that allows true spontaneity and the expression of authenticity.

Introduction

Scientific theories are not static. They develop and change. Some tenets are added, some are refuted and taken away. Hopefully there is progress, which means that a better understanding of ourselves and our world is constructed. What is unique to the sciences is that the methods, standards, and goals are maximally objective.

Creativity studies have adopted objective methods, standards, and goals and have thus become quite scientific. Yet creativity studies are in some ways unique. Creativity is different from all other human behaviors and potentials, and this means that there are unique difficulties for scientific research on the topic. Few other research topics are as unpredictable as creativity. Indeed, creativity is by definition unpredictable because originality is required. If something is original, it is unlike everything that came before it and is in that light unpredictable.

An enormous stride toward scientific respectability was made when J. P. Guilford, President elect of the American Psychological Association, argued so convincingly for empirical studies of creativity. He described creativity as a natural resource and pointed to the pressing need to invest in both its study and its encouragement. He also described various methods for the study of creativity, or at least for the study of creative potential. His distinction between divergent and convergent thinking has proven to be quite useful and, although it has been around for decades, is still cited with regularity. Another large step was taken at the *Institute for Personality Research and Assessment* (IPAR), not long after Guilford's Presidential address in 1950. Objective information about architects, writers, and various other professional groups was collected at IPAR, mostly with reliable personality inventories and tests of cognitive skill and style. In this manner a great deal was learned about domain differences, and all kinds of objective information about those creative professions was reported in the psychological literature.

Personal Creativity and Optimal Objectivity

The theory of personal creativity is much newer than the work at IPAR and other seminal efforts. It differs from them because it views the highly objective work to be exaggerated. It suggests that we can be too objective about creativity, and if we are, we lose the most important part of creativity, which is in fact personal and is therefore not entirely amenable to objective study. This may sound like an extreme claim about what is most important but it is based on the fact that personal creativity is required for

[☆]*Change History:* August 2019. Mark Runco updated affiliation and clarification was added to distinguish personal creativity from social creativity. The discussion of personal creativity as related to but distinct from self-actualization was extended. This article is an update of M.A. Runco, Personal Creativity, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 220–223.

everyday and ordinary creative problem solving—and required for world class creative achievement. World class creative achievement certainly requires more than personal creativity, including persistence, determination, large and diverse knowledge bases, and social impact, but it starts with the same personal processes that characterize everyday and ordinary creativity. Personal creativity is, in that sense, a prerequisite to all creative behavior. This article briefly describes the theory of personal creativity. Since it was developed largely as a response to social and product views of creativity, it begins with a summary of them, and thus puts personal creativity into context.

Product Views of Creativity

Products represent one of the primary strands in creativity studies. The other strands, according to the 4P framework, include process, person, and press (or place). There really are several product strands. One focuses on tangible results of creative work. There is, for example, a detailed 'matrix' for assessing products which can be used with all kinds of things, from chairs to new tools for writing. Robert Weber has also presented detailed analyses of individual products, though his interest seems to be more in invention than in isolating the characteristics of creative products. Inventions certainly represent a good example of creative products. A list of creative products would also include works of art (e.g., paintings), compositions, publications, presentations, performances, copyrights, patents, motion pictures, films, videos, computer software, 'apps' for cellphones, designs, and video games.

Many of these imply that product research involves only the work of adults, but checklists of productivity have also been used successfully with adolescents. These tend to be used as criteria in studies of predictive validity or in longitudinal research. Almost always the score provided by such checklists reflects the quantity of creative work (the number of products, and perhaps the number of awards as well) rather than their quality. Other times single products, such as chairs or inventions, are entirely disregarded and the issue is on *productivity*. Here the products themselves are not important at all; the only concern is with the count of or quantity of things produced. Research using productivity may not even identify the products; it may just analyze some number that represents how many things each creator produced. Not surprisingly, this kind of research is often archival. It may involve an analysis of age, for example, and thus look to encyclopedias or other records to see how many things tend to be produced when the creator is in his or her twenties, in comparison to how many are produced when the creator is in his or her thirties, forties, fifties, and so on. This kind of developmental comparison is interesting and shows that different domains of creativity seem to have different peak ages. There are questions with this line of work because the focus is on counts and productivity and not creativity *per se*.

Social theories of creativity take quality into account by examining judgments or attributions of creativity, originality, aesthetic appeal, and effectiveness. Some of this work is historical, in which case the issues mentioned above are still apparent. But sometimes judgments of products are obtained in experimental research and used as data. Judges in the consensual assessment method, for example, are explicitly asked to rate poems, collages, or the like for creativity, in which case there is a reliance on the product but the concerns with historical research (e.g., "cohort differences" and the like) are avoided. Obviously none of the product research, historical or otherwise, says much of anything about the processes used by the creators. This is an overarching drawback of all product research.

Systems theories of creativity, which are quite popular, assume that attributions by judges are required of all creative work. In the best known systems theory of creativity, an individual produces an original idea, and if its value is recognized (which assumes that the domain and culture value work in that domain), the idea may become known by others working in the field. If it is truly a good idea, it may change the way people (both laypersons and experts) think, and thus become part of the universal knowledge base. Individuals entering the domain at that point will be exposed to that idea as a part of the existing dogma, in which case the idea has gone the full cycle, from a person, to the field, to the domain, and then to other individuals. In the extreme view of this kind of systems theory, a creative idea is only creative when it survives the entire system and has interpersonal impact.

There are several problems with product, social, and systems views of creativity. Some are circumvented by the theory of personal creativity. Indeed, the theory of personal creativity was developed in direct response to what was seen as an exaggerated and unrealistic use of products and social attributions and judgments in theories of and research on creativity. Put differently, the theory of personal creativity was proposed to insure that the scientific study of creativity does not go too far in the direction of objectivity. Social and product theories of creativity are highly objective – products can be counted, inter-rater reliability easily determined – but too often they exclude much of what is most important about creativity.

The most notable problem with product and attributional theories of creativity may be that they focus on the results of creative work – the products or performances that result from creative efforts or the reactions by some audience to the creative person or the products. They dismiss the process used to be creative. This is unfortunate because if we really want to understand creativity in a way that will allow its encouragement, the process and underlying mechanisms must be precisely identified. Product and social theories do not allow that. They focus on reactions rather than on creation.

A second problem involves historical shifts and revisions. The basic idea here is that attributions of creativity change. They vary from era to era. This kind of variability indicates that social judgments are unreliable. That is exactly the way to describe the issue because reliability is defined in terms of consistency and stability. How can we rely on social judgments if a person is deemed creative at one point in time but not creative later? Examples of this are easy to find (e.g., Rembrandt). Clearly social judgment is

indicative of more than creative talent. It reflects many factors that are extraneous to creative talent (including luck!) and are really just indicative of fame, reputation, and impact.

Defining Personal Creativity

The theory of personal creativity focuses on the individual. No impact or reputation is required, which separates personal creativity from social and systems perspectives. Personal creativity is, on the other hand, congruent with the humanistic view. As exemplified by Carl Rogers and Abraham Maslow, humanistic views of creativity emphasize self-expression and self-actualization and de-emphasize products, attributions, and the like. Both Rogers and Maslow eventually concluded that creativity and self-actualization are inextricable from one another. That suggests a divergence of the theory of personal creativity and the humanistic approach. The latter is tied to a definition of psychological health that is not a part of the former—at least so far.

Probably more important is that the theory of personal creativity makes precise predictions about the mechanisms that are required for all creative achievements. As implied above, this mechanism is involved not only in children's creativity and the everyday creative problem solving of noneminent persons as they strive to solve large-scale problems or produce world-shaking work that is used by eminent creators as they strive to solve large-scale problems or produce world-shaking work.

Personal creativity involves (a) the construction of original interpretations of experience, (b) the intention to construct and use those interpretations, and (c) the discretion to recognize when to rely on original interpretations and when to rely on rote and conventional thoughts and actions instead. On a behavioral level it is discretion that is necessary for the individual to know when to be creative and when to act in a conventional fashion instead.

The first of these – the construction of interpretations – can be understood by considering how *sensation* differs from *perception*, on a cognitive level. Sensation is entirely dependent on the five sensory systems. Each of these (sight, smell, taste, touch, or hearing) brings experiential data into the cognitive system. The sensory systems do not alter data in any way; they merely detect information and bring it in, where it can then be processed. The information brought into the cognitive system via one of the sensory systems is therefore raw data. At that point the cognitive system can attempt to make sense of it. This is where perception begins. At that point information is analyzed, translated, transformed, considered, compared, and so on. All of this allows the individual to construct an understanding of his or her experience. The key point is that sensation differs dramatically from perception in that the first uses only raw data and the second transforms that into meaningful information. The transformation may occur in various ways, but they key is that it allows the construction of interpretations. Indeed, an *interpretation* is synonymous with the construction of meaning. That is the process that supports personal creativity. If the construction of meaning – the interpretation – is original and effective, it is creative. It is creative only on a personal level, but it might later be made social or elaborated into some sort of product. At first, it is unshared personal creativity.

The process used to construct interpretations was viewed as *assimilation* by the developmental cognitive psychologist Jean Piaget. Assimilation is not the same as adaptation, which, for Piaget, also involved accommodation and changes in cognitive structures. In fact, creativity is distinct from adaptation in a number of ways. Creativity can be proactive, for example, while adaptation is by definition reactive. Creativity can even be maladaptive, as is suggested by the dark side of creativity and the destructive tendencies of some creative individuals. Assimilation is only one part of adaptation. It is defined as a cognitive manipulation and alteration of information. It is what is known as a top-down process in the cognitive sciences and is manifested whenever a personal interpretation is constructed. Interpretations are constructed; they are not merely bottom-up representations of the external world. Individuals actively construct interpretations. They do not merely find them in the environment nor simply remember them.

None of this implies that all thinking is creative. As people age they develop assumptions, routines, and habits, and much of their behavior depends solely on them. These are not original. Occasionally we do mindfully construct an original interpretation that is also effective. That is a creative act. We may then elaborate on it, refine it, apply it, and perhaps even share it, and it might eventually make itself known in the form of a product or performance, in which case it is possible that it is socially recognized as creative. But at first it is just a new interpretation. It is a personally creative act.

There is research on individual differences in the use of creative interpretations. Gudmund Smith, for example, developed a technique to assess interpretative tendencies, or what he calls *percept-genesis*. This technique involves presenting ambiguous figures to individuals and asks them for possible interpretations. Since the stimuli are ambiguous, varied interpretations are possible. Results from several studies confirm that creative persons are able to construct meaning with less information, when the stimuli are more ambiguous. There are age differences, with less creative performances at age 7 and 12. Another drop often occurs in middle age. Smith and colleagues have reported good reliability and several kinds of validity for this method in the *Creativity Research Journal*.

There is also relevant empirical research on self-actualization, but keep in mind that personal creativity is not identical with self-actualization. Personal creativity is not dependent on the fulfillment of lower level 'needs' as is assumed by humanistic theories, and personal creativity is not necessarily tied to psychological health, as is the case for self-actualization. That being said, there are instances where the distinction between personal creativity and ill-health are quite clear. The originality that is expressed by psychotic individuals is not creative, for instance, in part because it is not an attempt to understand the world and not intentionally constructed, as is required by personal creativity. As stated above, the original interpretations of experience that contribute to personal creativity are intentional.

Contrarianism, blind nonconformity, and other forms of unconventional behavior are also distinct from creativity. They might lead to originality but they are not at all good indicators of creative talent. Truly creative individuals tend to the unconventional, but the vast majority of them also fit well into society. They are able to do so, even though they have original insights, because they exercise their *discretion*. They know when to be original and when to fit in. They are not blindly original, out of control in their originality. Frank Barron described creativity very nicely, in 1995, as ‘controlled weirdness.’ All of this reinforces the idea that creativity is not equivalent to originality, and that sometimes original individuals are not creative. This is why the theory of personal creativity states that the individual constructs original and effective interpretations, and why it also recognizes intentions and discretion.

Enhancement

The fact that discretion is a part of personal creativity suggests a method for enhancement. That is because techniques have been developed to encourage and exercise discretion. These techniques have been used with the hopes of facilitating the development of moral reasoning skills, but since they focus on discretion, there is every reason to believe that they could be adapted to creative thinking as well. If they are effective, individuals should recognize that it is good to be original, but only some of the time. This would parallel the recognition that it is good to fit in, some of the time, or to use the terminology from the research on moral reasoning, it is good to be conventional, some of the time. It is also good to be *postconventional*, which is the most mature level of moral reasoning. Postconventional individuals understand rules and conventions, and to take them into account when making decisions, but they think for themselves. This allows mindful action rather than either blind conformity or blind originality. It also allows originality to work with discretion.

Another approach to enhancement emphasizes (a) providing opportunities for self-expression and originality as well as (b) appropriately rewarding and (c) modeling those same two things, self expression and originality. Modeling is especially relevant to personal creativity because it has a twofold impact: it provides actual examples of creative behavior, which can be imitated, and it demonstrates that creativity is a valuable thing. It thus communicates appropriate values. These values are critical for intentionality and the enhancement of creativity. If individuals do not value creativity, they will not put any effort into being creative, nor try to develop creative skills. They will not invest in their own creativity. They simply will not appreciate it and thus will not care about it. But if individuals see the value of creativity, they will try to be creative and try to become more creative. They will appreciate it in others as well. The value of creativity can be communicated via creative models, including parents, teachers, and supervisors.

Conclusions

The most important part of personal creativity is that it is universal. It is not just a part of the creative efforts of ordinary people and everyday actions, but also plays a role in eminent creativity. It does not just describe what an individual does, but it also describes the efforts that precede and are required for socially recognized creativity. Recall here that personal creativity precedes attributions of creativity and the completion of creative products. All creativity begins with the construction of original and meaningful interpretations. These may go no further. They remain personal. Or they may be elaborated, tweaked, shared, and have an impact, in which case they lead to social creativity.

A second important part of the theory of personal creativity is that it attempts to get at the actual mechanism that is involved in all creative work. This mechanism is hypothesized as interpretive and assimilatory. Given that everyone can assimilate, this underscores the universal nature of personal creativity. Admittedly, many people put less and less effort into originality as they age, but that simply means that some people rely more and more on habit and routine as they age and exercise their creative self-expression less and less. With that in mind the practical implications outlined above are especially noteworthy. They offer techniques that may counter the tendency toward habit and routine and encourage discretion and the intention to be creative and to develop creative skills.

Introduction and Construct Conceptions

Psychologists and other researchers have examined the relationship between creativity and personality for well over half a century. During that period, conceptions of personality have evolved greatly as have those of creativity. Discussing the relationships between factors and facets of personality and elements of creativity requires a bit of initial clarification and groundwork.

Understanding the context and evolution of thinking on both sides of the personality-creativity connection provides a grounding to appreciate current research and conceptions surrounding the relationship. In this entry, personality will be considered using the most common, research-based framework of the day: The Big Five model. Over the past twenty years this has evolved to be the most commonly employed framework for assessment in studies of creativity and personality. Research-based conceptions of creativity have remained more varied and nuanced during that time, but commonalities can be extracted for clarity. The definition of creativity used here will be centered on novelty and usefulness, but the consideration of context will not be discounted. In addition to relating factors and facets of the Big Five personality framework to creativity, other relevant issues such as domain-specificity, issues of creativity measurement, and emerging future directions will be discussed.

Early Research

J.P. Guilford's 1950 address to the American Psychological Association set researchers on a path to more systematically clarify and describe the relationship between creativity and personality traits. In his speech, Guilford's stated aim was promoting the development of what he called "creative personalities." His premise was that if the underlying, intrinsic characteristics of highly creative individuals could be identified, these could be cultivated more broadly across settings such as schools to increase the general pool of creative talent. One should pause here briefly to appreciate the potential conflict of believing in a largely fixed personality while simultaneously aiming to develop such traits. However, to the extent that the development of creative talent begins with identifying it for advancement, there was definite value in Guilford's aims.

Creativity research in these early years focused on the study of creative eminence and the personal and personality characters of those eminent creators. This line of research involves working backward from lists and/or profiles of creatively eminent individuals and identifying common threads. Often this was done within a given domain, but sometimes the work was carried out across domains to find more generally applicable findings.

Frank Barron and Donald MacKinnon exemplified this sort of work with their examinations of highly creative individuals who were examined at the Institute of Personality Assessment and Research. Personality inventories and assessment were typically at the heart of studies of individuals as diverse as scientists, artists, architects, and writers (see Barron & Harrington, 1981). This work paralleled earlier efforts by Louis Terman and Leta Stetter Hollingworth to profile those deemed intellectually gifted based on intelligence tests in search of a defined gifted personality. In contrast to this work, MacKinnon and Barron viewed creativity as something to be developed, even in the absence of high general intellectual ability. (See Intelligence)

The first personality inventory commonly used in creativity studies was the Adjective Check List developed by Harrison Gough and Alfred Heilbrun (see Gough & Heilbrun, 1965). This instrument includes 300 adjectives. Through the completion of the

Adjective Checklist List, 37 resulting scales were developed. Among others, these varied scales included measures of basic psychological needs, method effects, and those factors associated with other relevant psychological constructs and potentials.

One of these latter “topical” scales related to the creativity personality. Gough went on to develop this into the Creative Personality Scale, an abridged scale limited to the 30 items most commonly associated with creative achievements across multiple domains (see Gough, 1979). On the scale, subjects are asked to indicate whether each given adjective describes them. Some responses are scored positively for creativity (e.g. humorous, insightful, original) while others are scored negatively (e.g. cautious, conventional, narrow interests). These scales are still commonly used in clinical psychology and counselling settings to assess individuals. While the Creative Personality Scale has declined in use as a primary measure of creativity in research settings, it remains commonly associated with convergent validity studies carried out on new creativity measures. Its persistent relevance and usage for this purpose underlines the foundational belief among psychologists that personality and creativity are intertwined constructs.

Toward Factor-Based Approaches

Gough’s Creative Personality Scale offered, and continues to be, a relatively simple way of assessing creative potential. As suggested, this offers clinicians and diagnosticians an avenue to quickly assess creative potential. However, in research settings, the use of Gough’s scale has diminished. Two primary reasons account for the decline. First, since the scale was specifically designed to measure creative potential, there was no means to relate that underlying potential to other psychological constructs without the use of secondary measures focused on those constructs. That is, the creativity-personality connection was already assumed by the measure. Second, much of the research into personality was moving toward the use of factor-based theories of personality in studies related to other constructs. Rather than treating personality as a laundry list of distinct characteristics, psychological researchers were aiming to find higher order structure and factors that could account for variations in personality. In turn these higher order factors were being used as the level of analysis when determining correlations to other constructs.

Hans J. Eysenck was the first to apply this factor-based view of personality to the study of creativity in earnest. His first theory of personality focused on two higher order factors: extraversion and neuroticism. While this theory was developing on a parallel timeline to work of Gough and others, Eysenck applied extraversion and neuroticism to effectively create personality types in the vein of work by Katherine Cook Briggs and Isabel Briggs Myers carried out in the early 20th century.

Later he added psychoticism to his theory as a third personality factor and investigated the relationship of each factor to creativity (see Eysenck, 1993; Eysenck, 1994). His primary focus on psychoticism contributed to the controversial notion of a relationship between mental illness and creativity as well as provided grounding for theories of malevolent creativity. Results of studies on psychoticism highlighted the complexity of relationships in creativity studies in that most results are U-shaped. That is, most often, the highest creative output is generally associated with a moderate level of psychoticism with both high and low levels of psychoticism being associated with lower creativity. Furthermore, in addition to direct effects, Eysenck suggested that elements of personality often interacted with aspects of intellect and intelligence to influence levels of creative output. This has been borne out by a large body of subsequent work (see Acar & Runco, 2012). (See Bipolar Mood Disorders and Schizotypy)

The Big Five

While the theories of Eysenck moved research of personality and creativity to a more factor-based focus, his heavy focus on psychoticism held back broad applicability. There were also concerns that three factors did not fully capture individual personality. Given the interconnections of personality with a host of psychological constructs, a more complete conception of personality was desired.

Work coalesced around a Five Factor Model. Although this sort of model had been proposed earlier by Lewis Goldberg and others, Robert McCrae and Paul Costa are the researchers most commonly associated with this conception. The NEO inventory by McCrae and Costa and International Personality Item Pool by Goldberg are the most common sources of items in studies of personality. The Five Factor Model includes openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism.

Openness to experience is conceived as related to the level of one’s engagement in new ideas, the depth of discussions and analysis desired, and an interest in that which is aesthetically pleasing or enriching. Innate, natural curiosity when presented with new situations is also captured in this factor. (See Personality: Openness) Conscientiousness is associated with goal-setting, aspects of self-discipline, and one’s level of personal reliability. Extroversion is associated with people who make themselves visible or are highly interactive with others. Those high in extroversion tend to prefer a breadth of experiences rather than a depth in certain areas, if given the choice. Conversely, introversion is associated with a preference for depth and limited interaction with others (See Personality: Introversion) Those who are more agreeable think more collectively than others and are generally more flexible, sympathetic, and forgiving in their interactions with others. Lastly, neuroticism is associated with those having a high-strung nature, more nervousness, and a general lack of emotional stability.

With the Five Factor Model as the dominant conception used in personality, framing the relationship of personality to creativity in this context should be a goal to maximize applicability. The first seminal work to make this overarching connection was carried

out by Gregory Feist (see Feist, 1998). In his meta-analysis, he synthesized the results of creativity-personality studies carried out in the artistic and scientific domains. Feist examined personality differences among three groups: scientists versus non-scientists, creative versus non-creative scientists, and artists versus non-artists. Each group included over two dozen studies for comparison. His analysis brought together these studies, carried out over decades with varied conceptions of personality, into a clearer, more concise set of results. In and of itself, the re-characterization each personality measure into a Big Five framework offers an instructive guide for carrying out such meta-analysis in personality studies beyond those related to creativity.

The results which emerged confirmed previously held beliefs and raised new questions. Taken in total, the most common positive relationship to creativity was found with openness to experience. Extraversion was a relatively close second. Both personality factors were previously well-established in the creativity literature and continue to be beliefs about their connections remain foundational beliefs. The smallest magnitude effects were seen with neuroticism and agreeableness. Generally, these were negative.

Perhaps the most striking findings in the Feist analysis related to conscientiousness. In two of the three analyses, it had the highest positive effect and in the other it had the strongest negative effect. This raises important questions about the nature of personality factors and creativity conceptions. An understanding of how and why each personality factor relates to creativity, an understanding of domain specificity, an appreciation of method effects based on creativity measurements used are all needed to illuminate the personality-creativity relationship more clearly (see Puryear, Kettler, & Rinn, 2017). (See Science and Creativity)

Factors and Facets

To this point when the word factor has been used to describe an element of personality, it has been intended to connote a group or cluster of more specific expressions of personality. Sometimes in the research literature the word factor is used somewhat interchangeably with the word facet, though doing so loses a bit of meaning. Here, and in much of the literature, the word facet is used specifically to describe underlying groups of related traits. Each of the Big Five factors can be conceived as containing six underlying facets (which group into two correlated aspects). These thirty facets have slightly different names against Five Factor conceptions. For consistency the names used here will be based on the NEO Inventory by McCrae and Costa. Ultimately, while using the Five Factor model helps to determine what level of a personality factor is associated with an individual, the underlying aspects and facets provides a glimpse into the how and why of the personality-creativity relationship.

Openness to Experience and Creativity

The openness to experience personality factor contains aspects referred to as openness and intellect. Openness is further broken down into facets known as fantasy, aesthetics, and feelings. Within intellect the three facets are actions, ideas, and values. Of the Big Five personality factors, no other factor comes close to openness to experience in terms of a tie to creativity. A recent meta-analysis suggested that of the variance in creativity that can be explained by a Five Factor model of personality, openness to experience can capture roughly three-quarters of that effect by itself. The strong openness-creativity relationship is so ubiquitous in creativity studies that sometimes openness to experience itself is used as a proxy for creativity in lieu of a specific creativity index.

McCrae specifically studied the links between openness to experience and creativity and suggested three possible links for the common finding, which Feist reiterated in his seminal work (see McCrae, 1987). The first is a matter of personal interest. Individuals with high openness may gravitate toward certain sorts of open-ended tasks like problem solving and problem finding simply because they have a proclivity to tinker at such tasks. Interest breeds success which in turn breeds further interest. Second, there is ability. Individuals with higher intellect scores may be more likely to have more developed cognitive abilities allowing them to score higher on creativity measures such as divergent thinking tasks which are scored for the fluency and flexibility of ideas present in a set of responses. Third, more open people may simply want to have a broader range of experiences because they crave novel sensations. Seeking out these sorts of sensations may help them in situations requiring creativity thinking since they will have a broader base of ideas from which to draw. (See Novelty)

An analysis of the facets themselves also suggests why there might be such strong connections. Creativity is often conflated with artistic pursuits (see "Art Bias") so it seems logical that an interest in aesthetics would correlate positively with creativity. Sample items for this facet might ask an individual to rate their belief regarding the importance of art or if they simply like a certain kind of creative product, like poetry. The fantasy facet relates to imagination which also fits into a general conception of creativity. Items in this facet might question whether an individual finds themselves daydreaming often or whether they often come up with new ideas such as how to use some common object. This item is related to how well a person would do on an alternative uses task, making the likelihood of a relationship to creativity high.

Facets in the intellect aspect also show an intuitive connection to creativity. The ideas facet relates to one's interest in deep discussions or for solving complex problems. The actions facets questions one's beliefs on change and routine. Recent research suggests the openness aspect is more related to creative achievement than the intellect aspect despite the success the latter has predicting fluid aspects of intellect. Additionally, recent work by Scott Barry Kaufman and others suggests there may be differential effects of openness and intellect depending on domain (see Kaufman, 2013). Specifically, across four samples, openness appeared more related to artistic creativity while intellect was more related to scientific creativity. This dichotomy is similar to Feist's findings of differential effects for the conscientiousness factor across types of samples. While they don't deal with the usefulness/appropriateness

components of creativity, taken together the facets of openness to experience are natural kindling for sparking unique and novel ideas which are a necessary condition for creativity.

Conscientiousness and Creativity

Within conscientiousness the aspects are industriousness and orderliness. Achievement-striving, self-discipline, and deliberation are the aspects under industriousness while competence, order, and dutifulness make up orderliness. A recent meta-analysis which examined studies of personality and creativity found the mean effect of conscientiousness on creativity to be incredibly small ($r = 0.02$) across over 150 correlations including nearly 60,000 participants. For context, the predictive power of openness to experience was about 250 times greater. Remember, however, that in the Feist meta-analysis, the strongest positive predictor of scientific creativity was conscientiousness, while it was the strongest negative predictor of artistic creativity. It is possible that the observed overall effects which suggest indifference to conscientiousness when predicting creativity most likely require further investigation and nuanced understanding. By examining the aspects and facets of conscientiousness, one gains insights into how conflicting findings may come to be.

Industriousness is related to hard work, a focus on the avoidance of mistakes, and completing tasks rather than wasting time or procrastinating. Studies of scientific creativity tend to take a holistic view of a career and most often use the number of patents or publications in one's field as a measure of creative output. The attention to detail and dedication required to earn patents or publish scholarly work gives clarity to the ideas that the scientifically creative would be high on industriousness and therefore conscientiousness. While these qualities may also be needed in some artistic pursuits, the orderliness aspect can be rationalized as a stronger predictor of artistic creativity. Breaking rules and conventions combined with an openness to disorder and a bit of chaos are the antithesis of the orderliness aspect and could be argued to be at the heart of artistic pursuits. As the creative achievements of artists tend to be judged on the level of recognition received, it follows that the more novel (rule-bending), yet appropriate or useful (aesthetically pleasing), products would be judged more creative more often.

Extraversion and Creativity

Enthusiasm and assertiveness are the aspects within extraversion. Enthusiasm is related to activity-level, excitement-seeking, and positive emotions. Warmth, assertiveness, and gregariousness make up the assertiveness aspect.

While extraversion is a distant second to openness in terms of magnitude of correlation, the literature base routinely shows extraversion as a predictor of creativity. It is the second most-reported personality factor in creativity studies. In Eysenck's view (and the earlier views of Carl Jung), those with higher extraversion are more likely to seek outside stimuli as their default mode of being. This engagement with outside ideas can work synergistically with a general openness to experience leading to an increased likelihood of subsequent idea generation and/or tangible creative production. Put another way, while openness to experience suggests an interest in novel ideas and actions, extraversion suggests a willingness to take the leap of doing something about it. This logical, sequential connection is a likely explanation for the significant amount of extraversion's predictive power that can be captured by openness. Item wording may have difficulty delineating an interest in ideas from an active engagement with ideas.

Another relevant idea in Eysenck's conception notion that those high in extraversion repress or blackout details of some experiences, particularly negative ones while those who are low tend to ruminate on the details. Here is where conflicting logic prevails. Research suggests that those who can move past negative experiences or setbacks have higher levels of creative production suggesting high extraversion predicts creativity. Research also suggests that depth and thoughtfulness, particularly about one's own past experiences supports creativity meaning lower extraversion should be a better predictor. There is little research looking at the balance of these two concerns, but it can be reasoned that this conflict accounts for at least some discrepancies in the observed effects for extraversion. There may also be an issue of measurement in play as moving past negativity with continued engagement may be reflected in increased quantity of creative production. A focus on the details and personal connections to specific work may lead to an increased quality of creative production.

Specific aspects of extraversion in the Big Five conception of personality clarify the observed positive correlation with creativity. These links are more unidirectional than those associated with an Eysenck conception. Those who seek excitement are more likely to engage in novel activities and genuinely enjoy the resulting stimulation, leading to further and related engagement. Those with high extraversion are more prone to high levels of activity and positive emotions. Again, more activity leads to more production across domains. Humor is captured with the aspects of positive emotions. Humor can be nurtured through artistic and creative pursuits. (See Humor)

Other aspects of extraversion suggest a willingness to engage with larger groups of people and their ideas. At the same time, high extraversion individuals can take charge when a task needs leadership. In business settings research suggests employees are viewed as more creative when they can generate and take on ideas from others (as judged by their peers), but at the same time be willing and able to strike compromises and guide a creative project to completion (as judged by their employers). This example provides articulation for how extraversion furthers creativity in a real-world context. While the effects of extraversion are not as strong as openness, they are robust and practical, making them important considerations.

Agreeableness and Creativity

Aspects of agreeableness include compassion and politeness. Compassion is made up of trust, compliance, and altruism. Straight-forwardness, modesty, and tender-mindedness make up politeness. Of the five factors in the Big Five, none has shown smaller effects on creativity or has less extant literature than agreeableness.

The failure of aspects of agreeableness to link to creativity can be helpful in understanding the nuances how other factors and facets of personality influence creativity. Modesty and trust are two examples. Recall that high extraversion individuals take leadership roles in everyday situations. The non-relationship of modesty suggests it isn't an individual's personal opinion of taking on the role that matters, just that they do so. The non-link of trust suggests that while high extraversion interacts significantly in generative situations with others, a deeper trust of the other person is not critical - only the idea the person has. The lack of a link to tender-mindedness also suggests a parallel (lack of) focus. Overall views of personal interactions or value systems for dealing with people such as altruism simply are not as relevant for creativity as the specific ideas or products in a certain context. Agreeableness should be viewed as a factor of personality which functions on a different level than those factors which influence creativity.

Neuroticism and Creativity

Neuroticism, which is often referred to as lacking emotional stability, combines volatility and withdrawal. Self-consciousness, impulsiveness, and vulnerability combine to form the volatility facet while anxiety, hostility, and depression combine to form the withdrawal facet. Both an early focus of psychological studies of creativity on eminent creators and Eysenck's work on creativity contributed to the association of neuroticism (or lack of emotional stability) and creativity. Studies of well-known, often tortured, artists contributed to a focus on idiosyncrasies or elements of mental illness and subsequent association of neuroticism and creativity among the general public. Work by Eysenck and others linked extreme schizotypy and creativity as well (see Schizotypy, this volume) When looking at the overall literature, Feist found domain-based differences for scientist and artists though not as disparate in magnitude as those for conscientiousness. Artists were more likely to score high for neuroticism whereas scientists were more likely to score low. A more recent meta-analysis showed neuroticism to have a slightly negative effect on creativity across nearly 150 reported relationships.

As with conscientiousness, an examination of the aspects underlying neuroticism provides context to appreciate the relationship of neuroticism and creativity. Impulsiveness may play a similar role to extraversion in leading individuals to novel situations as it may help them "take a leap." Going with a thought to extremes may manifest more in artistic creativity than scientific creativity. As remaining calm in stressful situations is the antithesis of the vulnerability aspect, one can see how scientific creativity, and any project running on a deadline, such as a business workplace situation, would benefit from low neuroticism. In contrast, strong emotions such as anger and hostility may fuel creative works viewed as unique, powerful, or more meaningful suggesting a positive influence of neuroticism among artists. These contradictions necessitate further study and clarification, as well as highlight the need to consider aspects of measurement and creativity conceptions when evaluating the link between creativity and personality factors.

Creativity Conceptions and Measurement

The domain-based differences in the creativity-personality relationship framed by Feist highlighted the deeper issues of conflicting conceptions and differing measures of creativity. Jeb Puryear and colleagues examined the influence of these deeper issues while providing an update to the base of research included in the meta-analysis. Two primary questions were examined in this work: 1) How does conceived of creativity as idea-based or product-based change the relationship to personality? and 2) How does the nature of the creativity measure, as more self-reported or more externally-rated, link with changes in creativity-personality relationships? Differences across elements of divergent thinking (e.g. fluency, elaboration) and with respect to specific measures were also considered.

Measures of creative production were found to be predicted by as much as twice as much by personality factors as ideational measures. Openness to experience, conscientiousness, and neuroticism all had statistically stronger relationships when production measures were employed. Differences in openness were most striking where one measure of production, the Creative Behavior Inventory, was related to the openness factor by eight times more than the Instance Task, a measure of ideation ($r = 0.403$ versus $r = 0.164$).

Differences between creativity-personality connection were even more distinct when considering self-reported versus externally-rated measures. All five factors showed statistically stronger relationships on self-reported measures. It was reasoned that some of this could be an artifact of the measurement itself as personality is also most typically self-reported, but the extreme differences could not be completely explained away. Considering the findings of this meta-analysis, whenever one is considering the creativity-personality relationship, the types of measures and creativity conceptions must be considered. While personality theories have coalesced to a point of consensus across studies, this has not been the case on the creativity side of the relationship. Going forward, this must be considered when defining problems and research studies into creativity and personality to contextualize the work.

Conclusions: Beyond the Big Five

While the usefulness of the Big Five as a tool in personality research has not declined, over the past decade, researchers have begun to examine the utility of even higher order factors of personality. One such model is the Huge Two: plasticity and stability. Plasticity combines openness to experience and extraversion while stability combines conscientiousness, agreeableness, neuroticism. This higher order conception of personality is particularly useful in creativity studies since the factors within plasticity account for so much of the creativity predictable by personality while the stability factors have smaller and often conflicting effects.

Specific studies based on the Huge Two conception found plasticity was a significant predictor of creativity across types of measures and across domains where creativity is operationalized differently. Importantly, findings indicated that the elements of creativity that can be predicted by personality differ most clearly at this Huge Two level (see Karwowski & Lebuda, 2016). Plasticity and stability each predict creativity in their own way and capture unique effects. As research into the relationship of creativity and personality continues to evolve, one must be vigilant when considering the personality and creativity conceptions used. Some provide more generalizability. Some provide more clarity of explanation. One must know the difference.

Creative Self-Efficacy

Albert Bandura's work on self-efficacy has impacted a variety of fields of study. Bandura defined perceived self-efficacy as:

people's judgments of their capabilities to organize and execute courses of action required to attain designated types of performances. It is concerned not with the skills one has but with the judgments of what one can do with whatever skills one possesses

Bandura (1986), p. 391.

Within the field of creativity studies, work on the concept of *creative self-efficacy* (CSE) has rapidly developed. Although CSE represents a relatively recent area of study in the field, work on this concept represents one of the most active areas of scholarly work by creativity researchers interested in understanding the creative self.

This entry will provide an overview of creative self-efficacy starting with a brief discussion of how the construct has been defined, how work on CSE evolved in the field of creativity studies, and current conceptualizations and measurement approaches. The entry concludes with recommendations for future research.

Emergence of Creative Self-Efficacy in the Field of Creativity Studies

One of the earliest mentions of creative self-efficacy in the creative studies literature was a 1998 article by Jonathan Plucker and Mark Runco, in which they discussed the importance of researchers identifying task-specific and task-general aspects of creative production "during each creative moment" (Plucker and Runco, 1998, p. 37).

Four years later, Pamela Tierney and Steven Farmer published an influential study entitled, *Creative self-efficacy: Its potential antecedents and relationship to creative performance* (2002). They offered a definition of the construct, developed a measure, and provided empirical evidence indicating that CSE serves as a unique and significant predictor of creative performance.

Tierney and Farmer defined creative self-efficacy as *the belief one has the ability to produce creative outcomes* (2002, p. 1138). They measured the construct with a three-item scale (e.g., "I have confidence in my ability to solve problems creatively") measured on a seven-point scale (1 = very strongly disagree; 7 = very strongly agree).

Research regarding CSE rapidly expanded to include explorations of the construct in and across various cultural contexts and domains (e.g., business, psychology, education). Much of this research used Tierney & Farmer's initial definition or an adapted version of the concept and scale. Specifically, researchers examined correlates and antecedents of CSE, the role CSE plays as a mediator and moderator, and CSE's role as a unique predictor of various creative outcomes.

Of central concern for many creativity researchers is how well measures of CSE predict creative outcomes. Previous studies exploring this issue yielded variable and, at times promising, results ranging from virtually no variance in creative outcomes accounted for by CSE to evidence of moderate effects (see Beghetto and Karwowski, 2017 for a discussion). The relationship between CSE and creative outcomes were also examined in several meta-analyses. In an extensive review of work on CSE, Farmer and Tierney (2017) discussed the results of several meta-analyses, which indicated that CSE has been found to account for 8.4% to 20.25% of variance in non-self-reported creative outcomes and 20.25% to 45.99% of variance in self-reported creative outcomes (pp. 36–37).

Current Conceptualization of Creative Self-Efficacy

Recently, creative self-efficacy was conceptualized as representing one of a family of nested creative self-beliefs, which constitute one's creative identity (Karwowski et al., 2019). More specifically, creative self-efficacy represents a particular type of creative

confidence belief that works in conjunction with creative self-awareness beliefs (i.e., beliefs about one's strengths and limitations) and creative self-image beliefs (beliefs about one's creative aspirations and sense of creative self) to comprise an overall sense of one's creative identity.

Creative self-beliefs can be further distinguished along three different dimensions (Beghetto and Karwowski, 2017): *specificity* (ranging from global to specific), *temporality* (ranging from past to future oriented), and *stability* (ranging from static to dynamic). CSE falls on the more specific, dynamic, and future oriented sides of these dimensions. CSE beliefs are activated when people are presented with a creative performance task or prompted to judge their ability to perform creatively on a specific task or specific set of broader activities in a domain. An example may help illustrate the nature and facets of CSE beliefs.

Consider an instructional consultant who is asked to come up with creative ways for introducing two scientific topics that students have difficulty learning (e.g., buoyancy and sublimation). For the first concept, the designer responds, "I'm confident I can come up with at least three creative ways to introduce buoyancy." For the second concept, the designer responds, "I'm less sure about sublimation, I can maybe come up with one creative idea, but I'm much less confident about it."

As this example illustrates, the instructional consultant's CSE beliefs are triggered by the presentation of two specific creative performance tasks. Moreover, it illustrates how creative self-efficacy differs from other forms of creative confidence on the dimensions of specificity, temporality, and stability.

With respect to specificity, although the two tasks represent the same performance domain (i.e., instructional design in science education) the particular consultant's creative self-efficacy beliefs vary based on the specific nature of each task. Indeed, CSE beliefs can vary from task to task within and across domains. Researchers interested in understanding how different tasks within the same domain may result in different CSE judgements would therefore need to measure CSE using more specific measures, rather than a more global or general measure of creative confidence (e.g., "I am good at coming up with creative solutions to problems").

With respect to temporality, CSE beliefs are future oriented beliefs. CSE pertains to a person's confidence to perform creatively on an upcoming task, whereas more global creative confidence beliefs are based on retrospective judgments of performance (Beghetto and Karwowski, 2017). Empirical research indicated that global measures of creative confidence tend to be more strongly related to past performance, whereas task-specific measures administered prior to a performance tend to be stronger, unique predictors of creative performance (Pretz and McCollum, 2014, see also Karwowski et al. in press).

This is not to say that more global beliefs have no influence on CSE beliefs. Indeed, more global and retrospective creative confidence beliefs have been found to be related to task-specific beliefs, particularly when first approaching a task (Pretz and McCollum, 2014; Karwowski et al. (2019)). This makes sense because more crystalized confidence beliefs (i.e., developed, in part, from past experiences) can be thought of as contributing to the development of subsequent CSE beliefs. However, once a person engages with a task the more immediate and proximal CSE beliefs likely will play a greater role in predicting task performance.

Finally, with respect to stability, CSE beliefs tend to be more dynamic than other creative confidence beliefs. In fact, CSE not only varies based on the nature of the task but other factors including physiological state (e.g., how one is feeling), social persuasion (e.g., whether trusted others are providing supportive messages), vicarious judgments (e.g., seeing someone who is relatable model successful performance), and various other socio-psychological factors (e.g., personal or social supports or impediments to performing a particular task) (Bandura, 1997). In this way, CSE beliefs (like all efficacy beliefs) are more than simple reflectors of prior performance, because they are influenced by a variety of situational, social, and individual factors (Bandura, 2012).

Returning to the hypothetical example of the instructional consultant, the consultant's more general creative confidence beliefs likely would influence CSE judgments for each scientific topic. However, given the differences in the two topics, the CSE beliefs would differ when initially presented with each task and those differences likely would influence CSE and ultimately performance across the duration of task engagement. Fig. 1 provides an illustration of one possible trajectory of the consultant's CSE beliefs for each task over time.

Figure 1 Hypothetical example of CSE x task variations across time.

As illustrated in Fig. 1, the hypothetical designer's general creative confidence informs more specific CSE judgments. However, once two separate tasks are presented, CSE judgments become activated. Indeed, the designer makes two different judgments of creative performance based on the two different design tasks. CSE beliefs continue to operate and fluctuate throughout each subsequent phase of task engagement. In this way, CSE plays a key role in determining whether a person will even try to engage with the task and to what extent the person will stay with the task when facing challenges (Bandura, 1997).

CSE, conceptualized in this way, highlights the more nuanced and dynamic features of this creative confidence belief, which has implications for how it is assessed in studies. The following section highlights some current approaches for studying CSE.

Current Approaches for Studying Creative Self-Efficacy

As mentioned, creativity researchers traditionally measured creative self-efficacy beliefs using more static and general measures. Consider the following global measure of, which uses three items rated on a five-point scale (1 = not true; 5 = very true) scale (Beghetto, 2006, p. 450): *I am good at coming up with new ideas; I have a lot of good ideas; I have a good imagination*

Although this global three-item measure (and scales like it) can provide some insights into people's creative ideational confidence, such measures tend to fall short in capturing the more nuanced, situated, and potentially volatile nature of CSE. Consequently, the predictive strength of such measures on creative performance likely will be weaker than more focused and specific measures of CSE. Indeed, as Bandura (2012) explained, global measures of self-efficacy usually "bear weak relation both to domain-related self-efficacy beliefs and to behavior" and thereby "have problems of predictiveness" (p. 17).

This does not mean that existing scales that measure global creative confidence have no value. Rather, the value of such scales likely will be realized when used in conjunction with more tailored and dynamic measures of CSE. As mentioned, a recent study by Karwowski et al. (2019) found that more global measures of creative confidence were predictive of more tailored creative confidence measures, which indicates that global measures do inform more task and situationally specific CSE beliefs. However, when it comes to creative task performance, more tailored CSE measures serve as stronger predictors of performance than do more global measures (Karwowski et al., 2019).

In addition to designing more tailored measures of CSE, it is also important to design tasks that have clear performance criteria. Indeed, in situations where the performance criteria of a task are ambiguous or a person has limited experience with a domain, the difference between more global and more specific measures of creative confidence beliefs likely would be negligible because the person's confidence performing a specific task would be largely based on a more general sense of creative confidence. As Bandura (2012) explained, task ambiguity interferes with people's ability to accurately judge their performance confidence.

Consequently, creativity researchers interested in developing a more nuanced understanding of CSE beliefs, likely would benefit from designing and including more tailored, specific, and dynamic measures and tasks in their studies. A brief discussion of recommendations and an example for how to design more tailored and dynamic measures and tasks are presented the sections that follow.

Designing More Tailored CSE Measures and Less Ambiguous Tasks

As mentioned, existing measures of creative confidence often lack the task and situational specificity necessary to elicit people's confidence to perform creatively on given tasks under particular situational demands. As Bandura asserted:

There is no all-purpose measure of perceived self-efficacy. The "one measure fits all" approach usually has limited explanatory and predictive value because most of the items in an all-purpose test may have little or no relevance to the domain of functioning. Moreover, in an effort to serve all purposes, items in such a measure are usually cast in general terms divorced from the situational demands and circumstances. This leaves much ambiguity about exactly what is being measured or the level of task and situational demands that must be managed. (2006, p. 307)

Creativity researchers have therefore started to recognize the importance of designing and using measures that are more tailored to the unique situational features of creative performance tasks. Again, such measures are not meant to replace existing creative confidence measures. Rather, more tailored CSE measures can be used in conjunction with more static and general measures to provide insights into how creative confidence beliefs and other related factors can work in concert with each other.

When designing more tailored CSE measures and performance tasks, creativity researchers may find it helpful to work from the following general recommendations (adapted from Bandura, 2006, 2012; Beghetto and Karwowski, 2017; Bong and Clark, 1999; Bong and Skaalvik, 2003):

- **Assess Perceived Capabilities.** *Measures should tap into people's perceived capabilities by using language focused on what people can do (e.g., "I am confident I can creatively solve three of these problems");*
- **Clarify Future Orientation.** *The future orientation of CSE beliefs should be designed into studies by making sure that measures are provided prior to (immediate or more distal) performance;*
- **Specificity of Measures and Tasks.** *Design tailored measures and tasks that assess performance in specific activity domains;*

- **Challenge and Constraints.** Items and performance tasks should include gradations of challenge or performance constraints to avoid ceiling effects;
- **Avoid Ambiguity.** Performance tasks and efficacy measures should avoid ambiguity and, instead, specify key features or levels of task performance;
- **Use Broader Range of Responses.** Use response scales that include a broad range of intervals, such as 0 to 100 or 0–10 (as they have been found to have greater predictive power as compared to scales with fewer points (see [Pajares et al. 2001](#)); and
- **Consider Dynamic Features.** When designing measures and tasks, recognize that CSE beliefs can change between initial measurement and performance; during different moments of performance; and across similar tasks within the same activity domain.

Creativity researchers can draw on the above recommendations to design more tailored and sensitive CSE measures and performance tasks for their studies. As mentioned, one way to think of creative confidence measures is that they run on a continuum from a more general to specific focus. As a result, even tailored CSE measures can range from assessing broader creative performance in a particular activity domain to specific performance on particular tasks within that domain. The key is that creativity researchers design tailored, multidimensional efficacy measures and performance tasks that represent the complexity of an activity domain and thereby elicit people's judgments of their capability to perform creatively (see Bandura, 2012).

Fig. 2 provides an example of what a CSE scale task might look like that has been tailored to a particular performance task.

As illustrated in **Fig. 2**, the CSE measure and task is tailored to a specific performance (i.e., generating a creative way to introduce the structure of matter to seventh grade science students). Moreover, this example aligns with the general guidelines discussed above. Specifically, it uses the language focused on what people can do (e.g., "Can come up with a creative way ..."), it is future oriented (i.e., CSE measured prior to performing the task); assesses confidence of capability to perform in a specific activity domain (e.g., CSE related to different concepts in teaching seventh grade science), includes various constraints that may help differentiate performance between people (e.g., grade level constraints, time constraints, spending constraints), minimizes ambiguity (e.g., provides clear description of task and performance criteria), and uses a broad range of intervals (i.e., 0–100 scale).

The dynamic features of CSE are also taken into consideration by minimizing the time from initial measurement to performance. A key benefit of designing a CSE measure tailored to be administered immediately prior to a performance task is that doing so addresses a key validity threat when it comes to assessing efficacy beliefs. Specifically, it can help eliminate what Bandura (2012) described as "temporal disparities between assessed self-efficacy beliefs and performance under conditions in which self-efficacy has changed in the interim" (p. 10). Consequently, measuring CSE beliefs in close proximity likely will enhance the accuracy and predictive performance of those measures.

With respect to assessing the creative performance on CSE tasks, researchers can use standard techniques in the field of creativity studies, such as the Consensual Assessment Technique ([Amabile, 1996](#)). Specifically, a panel of relevant domain experts (e.g., science educators) could assess the creativity of the ideas produced from this task. Moreover, this task could be used as one of several

Creative Way to Introduce the Structure of Matter to 7th Graders

How confident are you that you can come up with a creative way (i.e., unique and effective) to introduce a science unit on the structure of matter to 7th grade science students?

Here's some additional criteria:

- Your idea should introduce all the major concepts (i.e., atoms, matter, mass, volume, density, states of matter and phases of change).
- Your idea should describe a way of introducing this unit to 7th graders that takes a minimum of 30 minutes, but more than 45 minutes, and
- Each topic can use no more than \$50 of materials.

You will have a total of 15 minutes to come up with your creative idea for introducing the structure of matter.

Prior to generating your ideas, please rate your degree of confidence using number from 0 to 100 (0 = cannot do at all; 100 = highly certain can do).

<i>Can come up with a creative way to introduce:</i>	<i>Confidence (0 – 100)</i>
Atoms (definition and examples)	_____
Matter (definition and examples)	_____
Mass (definition and examples)	_____
Volume (definition and examples)	_____
Density (definition and examples)	_____
States of Matter (solids, liquids, gases)	_____
Phases of change (evaporation, condensation, freezing, melting, sublimation & deposition)	_____

Figure 2 Example of a CSE scale tailored to a particular task.

tasks to provide a broader representation of the activity domain and used in conjunction with other measures of interest to better understand the role CSE beliefs play in concert with various other related factors.

In sum, a more tailored CSE measure, designed to assess a person's confidence performing creatively on a specific task, likely will be a more reliable measure of creative confidence and, in turn, have a stronger association with actual performance.

Dynamic Methods

In addition to designing CSE items that are more tailored to specific situations and tasks, creativity researchers have also started recognizing the importance of designing studies that are more in line with the dynamic nature of CSE. Indeed, creativity researchers recognize that CSE, like many creative phenomena has dynamic properties (Corraza, 2016).

This is illustrated in the hypothetical example of [Fig. 1](#). The instructional consultant's CSE beliefs vary not only across the two different tasks, but change across the duration of task engagement.

Fluctuations in CSE beliefs makes sense theoretically. As discussed, people's creative confidence likely changes as they engage with the particular features of a performance activity. Depending on the task, their confidence may decline a bit as they encounter a surprising setback, steadily grow as they overcome challenges, and stay consistent through periods of task engagement, or some combination thereof. Consequently, researchers interested in understanding how such beliefs fluctuate within and across tasks have started to design studies using micro-longitudinal methods.

A micro-longitudinal approach refers to taking measurements with brief intervals between each measure in an effort to explore potential patterns and profiles of change in key variables of interest. With respect to CSE and related creative confidence beliefs, micro-longitudinal designs coupled with tailored tasks and measures offer researchers opportunities to identify and examine the more nuanced dynamics of CSE beliefs. Work along these lines is nascent, but recognition of using such methods to study confidence beliefs in and outside the field of creativity studies is growing ([Beghetto and Karwowski, 2019](#); [Marsh et al., 2019](#)).

Karwowski et al. (2019) for instance, used a micro-longitudinal design to explore potential changes in creative confidence beliefs and emotions across the duration of a creative writing task. Participants creative confidence and emotions were measured at three intervals: prior to, during, and following task engagement. Results from this study indicated that both creative confidence beliefs and emotions changed over the duration of the task. Specifically, creative confidence, on average, increased across the three intervals. Moreover, negative emotions tended to decrease and positive emotions tended to increase.

The findings from [Karwowski et al. \(2019\)](#) provide support for the dynamic nature of creative confidence beliefs and also suggest that as the participants in the study became more familiar and engaged with the task their creative confidence grew and, in turn, so did their positive emotions. Indeed, micro-longitudinal designs allow researchers to explore cross-lagged effects to examine directionality of relationships and, in this case the findings indicated that as participants creative confidence increased so did their positive emotions.

In sum, researchers interested in developing a better understanding of how of CSE beliefs change in and across tasks likely will find it beneficial to design and use micro-longitudinal designs in conjunction with more tailored tasks and measures. Doing so can help uncover the more nuanced and variable patterns and roles that CSE beliefs play in people's creative performance.

Conclusion

The purpose of this entry was to provide a brief overview of the emergence and evolution of creative self-efficacy research and theory in the field of creativity studies. There are few constructs that have generated as much attention in such a short period of time. This growing attention has resulted in exciting and important developments in how CSE has been conceptualized and studied.

As the field of creativity studies continues to evolve, creative self-efficacy likely will continue to play an important role in understanding factors that contribute to creative performance and the role that self-beliefs play in shaping people's creative identity and experiences.

Introduction

Passionate perseverance is central to most stories of creativity. One such example is Thomas Edison. Among his many creative products and nearly 2000 patents, the phonograph was his favorite invention. He refined it repeatedly over a period of 50 years. This groundbreaking technology was initially meant to be a scientific innovation for use in office work, but it was considered too complicated for ordinary office workers to use for dictation. It first recorded sound on pieces of tin foil that could be used only once. Over time, Edison was successful at refining the technology with reusable recordings and repurposing into a must-have entertainment device that families were willing to buy. This tech revolution shifted the way everyday people were able to enjoy music. Edison understood that creativity was not just producing a novel and valuable product; it took time and effort to refine and redefine his product. He also knew that it was imperative that as a creator he would be able to persuade the world that the phonograph was an innovation that they wanted to acquire. The combination of creativity and perseverance led to Edison's technological revolution.

A similar story played out in the 21st century with Steve Jobs and the Apple iPod. Jobs did not produce the first mp3 player, but the iPod was the one that made the leap to popular usage because of a combination of creative innovation and perseverance. From technological innovators like Edison and Jobs to small business entrepreneurs who need to persuade the world of their superior cupcake or consulting expertise, to artists who are forging new expressions, creativity requires the ability to persist in the face of conformity, opposition, and the indifference of the world.

Edison and Jobs are prototypical divergent thinkers because of their prodigious output of ideas. Divergent thinking has been the cornerstone of much creativity research since Guilford's clarion address at the 1950 American Psychological Association in which he called for the scientific examination of creativity in all of its complexity. Throughout the research into creativity, perseverance has played some implicit part in the conception of the construct, and the working of the creative process has clearly required some form of dogged persistence. In order to power through the identification of problems, the fluent production of novel and valuable ideas, the organization, synthesis, analysis and structuring of new ideas, and the final evaluation of which ideas to choose, it is clear that endurance is required.

The most prevalent way of measuring divergent thinking has been to determine the fluency, flexibility, and originality of ideational behavior. These tests favor those who are able to produce ideas in quantity. This has been an often-used proxy for creativity. Within this larger creative process, the creator must work through the obvious and mundane ideas, move onto the interesting and unusual, and converge upon the one that will be most fitting. Sternberg and Lubart conceived of creativity as a marketplace. A creative investor would find unknown and unpopular ideas to buy and would then invest energy and thought into refining them into marketable ideas that could be sold to the public. All of these conceptions of creativity require persistence!

In order to persevere in a creative pursuit it is critical to be intrinsically motivated and committed to the task. Some conceptions of creativity such as the pathway model, view persistence itself as one means of creativity (Nijstad et al., 2010). Historically based studies of famous creatives point to the tremendous output of prodigies who had to overcome personal and contextual barriers to become creative icons. Csíkszentmihályi's famous theory of flow (1996) is one explanation of how creators are able to push through a difficult process and manage to create. Hennessey and Amabile (1998) found that the delightful experience of flow—sustained attention to the creative process that seems to take place out of time (Csíkszentmihályi, 1996) promotes creativity through the intrinsic rewards of the process itself.

Sternberg's research found that creative individuals prefer thinking in new ways, are willing to rebel against constraints and insist on doing things their own way, and have an ability to switch between global and local thinking. These findings suggest that the types of problems and tasks preferred by creative thinkers may also require those individuals to exhibit both cognitive flexibility and perseverance in the pursuit of their goals. An important underlying assumption for personal attributes in the investment theory is that the individual can choose to nurture and exercise those attributes that lead to creativity. The attributes that Sternberg found important for creative functioning include openness to experience, risk taking, willingness to overcome obstacles, tolerance of ambiguity, and creative self-efficacy. The positive correlation between openness to experience and creativity is among the most robust findings in the literature. It seems logical that in order to become creative, one needs to be open to new experiences and ideas.

Environmental support also plays the important role of either rewarding creative ideas or devaluing them. Creativity does not occur in a vacuum; the cultural context determines whether the idea or product is indeed novel and useful. History tells us that

cultural gatekeepers do not always accept creative ideas. The individual must often persevere in the face of a resistant environment in order to sell the new idea to those who prefer status quo. An environment that is particularly nurturing of creativity can cause a flowering of creativity, such as the Italian Renaissance. However, even in a resistant or indifferent environment creativity occurs when perseverance and intrinsic motivation push the creator forward. The creator is an agent who shapes and selects environments that are conducive to the creative process. However, it is the creator's endurance in any environment that determines, in part, the outcome of the creative process.

The outcome of creativity is the production of something that is novel and useful in some way. This may be an idea, a product, a business, an experiment, a solution to a problem, a great meal, or a work of art, among many other things. These creative products may not be immediately valued in the existing environment, and the creator must find, persuade, or create a market for the useful new thing. As the magnitude of the creativity increases and the sphere of influence increases, scientific, artistic, technological, and social breakthroughs can take place (Sternberg and Lubart, 1995).

The resources that make an individual creative also can have negative effects. In school settings, teachers may dislike the presence of creative students in the classroom because they can be seen as defiant, nonconformist, and difficult. The intrinsic motivation that leads to creative perseverance may also lead to the neglect of more mundane tasks in settings where standardization and conformity are expected, and the intense focus of creative perseverance can be perceived as obnoxious or aggressive.

In closely related research, there are two additional concepts: deliberate practice and self-regulation. Deliberate practice is focused attention designed to improve performance. Think of a virtuoso musician practicing scales or a professional basketball player working repeatedly on jump shots. It takes hours of precise and deliberate practice to shape that kind of expert performance (Ericsson and Charness, 1994). This deliberate practice is also tied to the ability to self-regulate.

Self-regulation, or the ability to decide how to shape one's own behavior and reactions, is a psychological construct similar to this idea. Self-regulation is rooted in Bandura's social cognitive theory in which individuals are viewed as agents who shape and select their environments in order to accomplish personal goals. This cyclical and iterative process of self-regulation includes self-monitoring, self-judgment, and self-reaction. Self-monitoring occurs when individuals are able to pay attention to their own processes. Self-judgment allows individuals to determine the value of the efforts. Finally, self-reaction is the response to all this information. Although the desire to accomplish a goal is important, self-regulatory skills allow the individual to accomplish the goal. Self-regulation is not a fixed trait; instead, it is a skill that is developed over time and with experience. Although beginning to practice a new skill is often externally motivated by an authority figure, a self-regulated practitioner is more internally guided than externally persuaded. When there are obstacles to accomplishing a task along the way to reaching the larger goal, the success of pushing through the obstacle builds the skills of self-regulation.

Other theorists echo these findings because the importance of cognitive flexibility and perseverance is present in nearly every conception of creativity. Guilford's idea of divergent thinking as the basis for creativity was the first and most influential basis for flexible thinking. Runco built on this foundation to develop the idea of ideational flexibility as a basis for creative ideation (Runco et al., 2001). An unusual take on this idea of ideational flexibility as a contributor to creativity is the dual pathway model; this model views creativity as a function of either cognitive flexibility or cognitive persistence (Nijstad et al., 2010). In a series of experiments, students were primed for either approach or avoidance motivation conditions with instructions.

For example, for an idea generation task, those students in the approach condition were instructed: "By generating ideas, you can gain time. The more ideas you generate, the more time you gain for the second task, making it easier to do that task well." Those in the avoidance condition were instructed: "By generating few ideas, you can lose time. The fewer ideas you generate, the more time you lose for the second task, making it harder to do the task well." Their creative tasks were rated for originality as well as for flexibility and persistence. To assess cognitive flexibility, the numbers of categories that were generated were counted and those with more categories of ideas were judged to exhibit more cognitively flexibility. To assess cognitive persistence, the number of times that students switched categories was counted, and those who switched less were judged to exhibit more persistence. It was found that individuals placed in the approach motivation condition accomplished creative tasks with cognitive flexibility, whereas those who were placed in the avoidance motivation condition accomplished creative tasks with cognitive persistence (Roskes et al., 2012).

Yet in spite of this inherent need for perseverance in creativity, it has not been typically measured in the literature. Recently, a new perseverance construct has gained traction in research circles as a possible means of operationalizing the perseverance necessary to drive creativity. That construct is grit.

History of Grit

Grit is defined as the perseverance and passion to pursue long-term goals, and as such, fits well conceptually into the idea of investing in unusual ideas in spite of opposition. Grit has captured the attention of researchers, educators, and the general public. When Duckworth (2016) first conceptualized this idea, it was grounded in positive psychology and based on research into self-control and conscientiousness. Duckworth developed her scale by focusing on populations such as college students in elite universities, West Point Cadets, and young Spelling Bee Champions. It was designed to reflect the characteristics of high-achieving individuals. The two versions of the scale (12-item and 8-item) each devote half of their items to consistency of interest and half to perseverance of effort which, when combined, represent the larger concept of grit.

Grit was shown to predict markers of success such as retention or grades, over and above those outcomes predicted by intelligence. Grit is related to conscientiousness, but its emphasis on stamina sets it apart from that construct, according to Duckworth.

Individuals with high levels of grit pursue long-term goals even without positive feedback. In studies of elite groups such as Ivy League undergraduates and National Spelling Bee champions, grit has been shown to be predictive of achievement above and beyond IQ. However popular this idea has become, there are detractors who have found that the construct of grit may be based more on perseverance or conscientiousness rather than a passionate higher order personality trait (Credé et al., 2017; Usher et al., 2019).

Grit has not been examined very much among diverse populations. Although early research into grit did not find ethnic differences, a recent study among African Americans has indicated that grit is a particularly strong predictor of college grades among male African American college students in predominantly White institutions (Strayhorn, 2014). Although Strayhorn's study did not compare African American students to students of other ethnicities, the strength of the findings does prompt the question of whether or not there might be ethnic differences in grit.

Duckworth's team reported a correlated two-factor structure (consistency of interest and perseverance of effort) for the scale. The grit scale has recently been used extensively, especially in research in education as a predictor of novice teacher effectiveness and in psychology as a predictor of psychological well-being.

Grit has grown in popularity as a measure across domains, and, as a construct, its definition holds promise of being a means to predict that passion and perseverance required for creativity. There have been some mixed research results regarding the efficacy of the measure of grit as conceptualized by Duckworth. Some researchers found that grit is more of a measure of persistence than of passionate persistence. Some of this may have to do with the items used to measure the construct that seem to indicate commitment and consistency of interests over time rather than the affective aspects of passion. Some researchers have even spoken of grit as perseverant grit. Abuhassan and Bates (2015) examined conscientiousness and effortful persistence and posit that grit is more representative of persistence than passion.

True (Creative) Grit

The use of grit as conceptualized by Duckworth has started being examined by creativity researchers. Grit was recently proposed as a measure of perseverance to be used in the operationalization of the Sternberg's investment theory of creativity (Rojas and Tyler, 2018). In this study, the psychometric examination confirmed Duckworth's factor structure of two separate factors, but the recommendation to use it as a unidimensional construct. In another recent study, grit was compared to teacher reports of grit and openness to experience as a potential predictor of creative achievement (Grohman et al., 2017). This study found that grit was not able to predict creative achievement among three samples of high school students in these regression models. The researchers also proposed that grit was likely a measure of conscientiousness. Other research (Reiter-Palmon et al., 2009) has indicated that conscientiousness is not a good predictor of performance in creativity, and this provides an additional caution for grit as a measure of creative perseverance. Although there may be a shortcoming of the measure itself, there is still a need to operationalize passion and perseverance within the creative process. The definition of passionate perseverance makes sense, but perhaps grit is not the best measure for predicting creative outcomes.

The Future of Creative Grit

Future directions to be considered include finding additional measures of perseverance within the creative process. Grit is conceptualized as a passionate pursuit of long-term goals, but the factors are meant to represent interest and effort. Another measure that more explicitly measures passion might be more relevant to the creative process. Interest and effort alone do not necessarily indicate passion, although they do seem to measure perseverance.

Another challenge with the grit construct is that it is meant to be a trait-level characteristic that is mostly stable over time and is domain-general. Within the creative process, it may be preferable to find or develop a measure of creative perseverance that is domain-specific. One means of addressing this could be to add domain-specific language to the items themselves or to provide a creative context for assessing one's own grit. Other considerations for measuring perseverance in the creative process might include measuring levels of creative autonomy, intrinsic motivation, or nonconformist identity. All of these factors may contribute to the ability to persist through the challenges of creativity.

Another area of exploration for creative grit would be an examination of grit within other well-established creativity constructs. For example, one helpful tool for examining creative grit might be to look through the lens of Rhodes four P's of creativity: the person, the product, the process, and the press/environment. Perhaps grit itself should be called perseverant grit as some researchers have started to do (Usher et al., 2019).

In addition to focusing on aspects that pertain to person, process, product, or press, another important consideration is the grit necessary to accomplish different magnitudes of creativity. What levels of grit would be required to navigate everyday vs. eminent creativity? How does the developmental process of creativity correspond to the development of grit?

These are just some of the future directions that might be indicated for grit within creativity research. The need to measure the passion and perseverance required to navigate creativity is clear.

Creativity and Introversion

Creativity is conceived of as one of the valuable human attributes that contributes to success in a fast-moving society. Many believe that creative people are capable of leading in the future, a world that will be full of unpredictability and complexity. For decades, a number of psychologists and educators have studied creativity from various perspectives. Understanding creativity by creative persons, processes, products and performances. Yet, creativity has been rarely studied in relation to introversion although a wide array of personality characteristics has been unveiled as personal variables contributing to creativity. Furthermore, extraversion, the opposite mode of introverted Is introversion of little importance of creativity?

This entry aims to endorse a premise that introverted personality sometimes contributes to creative performance and achievement. We first identify creativity in terms of (1) the process of creative finding and solving problems and (2) the level involving personal or every day to eminent or socially recognized creativity. We discuss the relationship between creativity and introversion by focusing on the roles introversion plays from the early stages of the creative process, and from personal to professional creativity. The creative problem finding and solving procedure is indispensable for achievement and success in domains, and particularly in business and engineering that call for innovative work in the present society. Creativity at the personal level also depends upon the creative problem solving procedure because everyone has to deal with finding and solving problems in real life settings.

This entry shows how introverted personality can help to stimulate creative thinking and leads to creative contributions. We include discussions regarding why introversion and introverted people are undervalued in creativity studies today.

Relationships Between Creativity and Introversion

What Literature Says About Introversion, Introverted People, and Creativity

Despite the ongoing argument whether personality is one's stable internal trait or developmental characteristic, personality is deemed the underlying basis of behavioral differences for individuals. In the studies of creativity, a various types of personality have been addressed as a stimulating force of creative achievement, yet little is known about introversion. The following section discusses introversion and creativity according to the three themes: Conceptions of introversion, characteristics of introverted people, and introverted characteristics found among professionally to eminently creative people.

Conceptions of Introversion

The conception of introversion was first introduced by Carl Gustav Jung in the early 1920s as a mode to explain one's attitudes towards the world. Jung identified introversion and extraversion in terms of the location of one's sources of energy, namely the internal world for introversion and the external world for extraversion. Some researchers defined introversion as the opposite personality facet of extraversion. For example, a dimension of introversion versus extraversion is included as one of the four personality modes on the *Myers-Briggs Type Indicator* (MBTI), which explains one's personality type in terms of responding to and interacting with the world around oneself. Sixteen personality factors similarly identified introversion versus extraversion as the tendency to move away from versus towards interactions with other people. Eysenck (1990) similarly defined extraversion in accordance with behavioral characteristics that involve sociability, impulsiveness, activity, carelessness, liveliness, jocularity, etc., as related traits. Introversion in his model is placed in the opposite end of extraversion identified by low levels of impulsiveness and sociability.

Introversion has been discussed according to the state of cortical arousal (Eysenck, 1967). Eysenck differentiated introversion and extraversion in terms of a state of cortical excitability that affects one's outgoing behaviors and social interactions. He claimed that introverts have higher cortical excitability than extraverts because the former has a lower threshold for arousal in the ascending reticular activating system (ARAS) than the latter. Corcoran (1964) found that after having lemon juice, profuse salivation was reported more from the introverted than extraverted people because the introverts had a lower state of ARAS activation. The low activation in the ARAS is associated with a low intensity of alertness and feelings (e.g., tired, weary, drowsy, powerless), while high activated ARAS triggers alerted, energized, courageous, and vigilant state of mind (Young and Pigott, 1999). Other results reporting introverted people's high level of cortical arousal confirm lower alpha rhythm amplitude, shorter latency of Wave V and faster conduction time between Waves I-III and I-V on the brainstem auditory evoked responses; and faster ABR wave V latency found among the introverts compared to the extraverts.

Differences in cortical arousal accounting for variances between the introverted and extraverted people originate from one's intentional attempt to hold an appropriate degree of arousal when responding to a wide array of stimuli (Eysenck, 1967). Introverted people are thus likely to avoid outer stimulations in order to keep their arousal to a minimum level (i.e., low arousal threshold), and extraverted people are the opposite, thereby being prone to pursuing excitement and social activities to increase their arousal. In this regard, the introvert outperforms in a low-stimulus environment (e.g., quiet mood, alone time), and his/her behaviors are manifested in a reserved and self-contained manner.

On psychometric scales, introversion is also measured as the opposite personality mode of extraversion. On the *Myers-Briggs Type Indicator* (MBTI), one of the four subscales measure one's inclination for introversion versus extraversion in terms of one's orientation towards attention. Individuals who prefer introversion are inclined to pay attention to their own inner state, ideas, thoughts, and emotions, and those preferring extraversion focus on the outer world. Eysenck and Eysenck's Personality Questionnaire (EPQ) measures the dimension of extraversion/introversion in terms of the level of impulsiveness and sociability. Individuals with higher score on extraversion are likely to be sociable, dominant, outgoing, and risk-taking; seek excitement; and act extempore. While, introverted people have the opposite characteristics with low levels of impulsiveness and sociability. Lastly, the NEO Personality Inventory, well known as the Five-Factor (or Big Five) model of personality measures patterns of one's behaviors according to the five dimensions of personality. In the model, extraversion is related to a great intensity of enthusiasm, and introversion is identified with low enthusiasm.

Characteristics of Introverted People and Creativity

Introversion has been rarely studied as an independent personality mode but has been addressed as the characteristics of individuals identified as introverted and/or as the opposite characteristics of extraverted people. Research has documented that introverted people are quiet, humble, and good at managing uncertainty; prefer to learn by listening; and feel comfortable working alone. They are highly sensitive, cautious in processing information; and persistent in solving complicated problems. In particular, introverts are likely to gain energy internally more than externally; spend considerable time preparing and incubating thoughts and ideas; and carefully respond to outer stimuli. They have a genetic disposition to longing for solitude because solitude invigorates to keep contact with one's own world, encourages to speculate on ideas, and stimulates creative imagination and innovation. Thus, introverted people prefer to have quality time thinking about their own ideas before sharing them with others and take action.

The above mentioned introverted characteristics were found among creative people (Feist, 1999 for summary), and particularly those who accomplished professional to eminent levels of creativity. Research showed that introverted tendencies, such as having alone time and attentional focus with great intensity, followed by a certain degree of social isolation are crucial for creative achievement. Introversion and social aloofness were found more for creative scientists than less creative scientists. This result supported the previous study that revealed introversion as the distinctive characteristic of creative scientists. Similarly, among the professional artists, securing time and space for being apart from other people was indispensable to producing creative ideas and artwork. The capacity to be alone encouraged creative artists to think, learn, imagine, and innovate, and solitude was therapeutic in the process of creative artwork. Ericsson and colleagues also reported that the highly achieved violinists spent substantial time alone for practice and that the best violinists practiced intensively more than the other groups of violinists (i.e., good violinists, music teachers) during the entire period of musical talent development. Deliberate practice is possible when one procures alone time to intensely concentration on work. It enables one to take apart from the routine and get playfully engaged in work, so that s/he can move beyond the current realm of stable performance that upholds the status quo and prohibits creative performance (Ericsson, 2006).

Researchers supported that deliberate practice is imperative to professional accomplishment (see Ericsson, 2006; Hayes, 1981; Kaufman and Kaufman, 2007). World class performers in various domains, such as chess, sports, arts, and science, for example, spent a decade of intensive preparation for creative achievement. Gardner's analysis of seven creative geniuses substantiated how intensive efforts for 10+ years devoted to creative work contribute to eminent achievement. Kaufman and Kaufman reported that it took an average of 10 to 13 years for writers to produce a masterpiece since they had started publishing work. Also, some creative scientists and writers were reported to spend 10 years reaching the ages to produce eminent work since their first productions. It is not clear if all these creative people were identified as introverted. It is likely that their introverted inclinations to long for personal time and solitude contribute to forming a sense of inner peace, facilitate self-reflection, and make it possible to get engaged in deliberate practice which ultimately fosters creative accomplishment.

Results are split whether introverted people lag behind socially. Examples include that the majority (2/3) of creative architects were identified as introverted. Yet, they liked to exercise control over other people, enjoyed being in a leadership position, and had

good social skills. In contrast, creative professionals in science and business were found to be introverted, preferred to be alone, and sought solitude.

Some anecdotal evidence endorses introversion as one of the distinctive personality characteristics found for creative people who obtain outstanding reputation for their creative work or lead today's business world. Examples include Ludwig van Beethoven, Wolfgang Amadeus Mozart, Franz Schubert, Johan Christian Bach, Michael Jackson, Vincent van Gogh, Pablo Picasso, Charles Darwin, Albert Einstein, Daniel Libeskind, Steve Wozniak, Mark Zuckerberg, Franz Kafka, William Shakespeare, Virginia Woolf, Kareem Abdul Jabbar, Emma Watson, Emma Stone, Mohandas K. (Mahatma) Gandhi, and Angela Dorothea Merkel. These are all creatively eminent and introverted people whose work have had a tremendous impact on the world. The following are some of the famous introverts who are quiet, shy, nervous, sensitive; prefer to be by oneself and work alone; and concentrate on work with great intensity, persistence, and passion.

Steve Wozniak, an American inventor and technology entrepreneur, well known as a co-founder of Apple, the world's largest information technology company, is a quiet business innovator. In contrast to another Apple co-founder Steve Jobs, an extraverted creative genius, Wozniak came up with ideas on his own, and believed in the importance of thinking and working alone. "I don't believe anything really revolutionary has ever been invented by committee ... I'm going to give you some advice that might be hard to take. That advice is work alone, not on a committee, not on a team," said Wozniak (Foran, 2015, p. 12). In fact, generally, Wozniak was reported to be by himself and worked alone until he developed his first Apple computer.

Michael Jackson, an American singer, songwriter, and dancer, was one of the most popular entertainers and best-selling musicians of all time. He was famously known as a very shy and private person who got nervous and would not (dare to) talk to people if he did not know them well. Christine "Coco" Decroix, a singer who translated Jackson's song "I just can't stop loving you" into French language recalled the moments when she met with Jackson.

At the beginning, I thought I was disturbing him and that my presence was too much. It's very embarrassing. And then, gradually, after he saw me a few times with Quincy, he started looking at me. Then he said, "Hello." He got used to me. He needs to be comfortable. When this happens, he is extremely caring though he is still worried whether everything goes well, if people are happy. This is the most considerate guy I have ever met. And what people don't know is that he has a lot of humor ("More about Michael," 2012).

Emma Stone, an American actress and an Oscar Award winner for her leading role in the 2016 film "La La Land" was a very nervous child and confronted a debilitating shyness and numerous panic attacks in childhood. She admitted that acting helped her to overcome her anxiety triggers because it enabled her to be less nervous about her own fears and granted her an outlet to reduce her anxieties through interactions with other people. She said, "Before any interview, I have to sit with myself for 5 min, breathe, and get centered because I get so nervous. Interviews are kind of like therapy except all your answers are being written down and printed. I always want to be on the other side of it" (McShane, 2017, p. 5).

Daniel Libeskind, a world-renowned architect who won the competition to be the master plan architect for the reconstruction of the New York City World Trade Center site, needs time alone for his creative work. He said that securing time apart from beloved family and other (significant) people is valuable because it serves as a foundation for his creativity. Time for reading poets, playing the musical instruments, taking a stroll down the street, and lying down under the tree were some of examples he referred to as imperative to build creative architecture (Meyers and Gerstman, 2007).

Mark Zuckerberg, an American technology entrepreneur who is known as a co-founder and a current chairman and chief executive officer of Facebook, an American online social media and social network service company, is one of the most famous introverted entrepreneurs. He is described as a classic introvert who lives in his own world staying up all night, focusing his attention on a subject he is interested in, and working alone. "He is shy and introverted and he often does not seem very warm to people who don't know him, but he is warm ... He really cares about the people who work here [Facebook]" said Facebook COO Sheryl Sandberg during the New York Times interview. Sandberg has been a great supporter of Zuckerberg who was portrayed as socially aloof and visibly nervous in public interviews. She has offered him social guidance to compensate for his introverted and sometimes less charismatic personality (Helft, 2010, p. 8).

Charles Darwin, an English scientist who is very well-known for his work on the science of evolution, and Franz Kafka, a Bohemian Jewish writer and one of the key figures in the 20th century literature are other influential introverts who spent a considerable amount of life time in solitude. As a child, Darwin enjoyed long, solitary walks and fishing for hours by himself. Kafka's extreme introversion was manifested in describing his desire to be alone while devoting to work. He said, "You [his fiancée] once said that you would like to sit beside me while I write. Listen, in that case I could not write at all ... That is why one can never be alone enough when one writes, why there can never be enough silence around one when one writes, why even night is not night enough." (Cain, 2012, p. 86).

The above examples support that introversion was evidently found among these eminent people and influenced their creative thinking and performance that have transformed their own domains and entire human life. Whether introversion is inherited or has to be a precedent condition for one's creativity is yet inconclusive.

Mechanisms of the Creative Process and Introversion

Understanding creativity by means of the model of creative process helps to identify contributing factors from start to end of creation. In the creative process model, numerous factors are involved in discovering and solving problems in a creative manner. These include a range of intrapersonal attributes, including personality, but few studies examined introversion and its engagement in the creative process.

Models of the creative process have suggested a stepwise procedure that provokes creative thinking. The renowned Dewey, Wallas, Osborn-Parnes, and Isaksen, Dorval, and Treffinger models are good examples that account for the creative process involving multiple steps. For instance, Wallas's model consists of preparation, incubation, illumination, and verification processes. Osborn-Parnes' model included mess finding, data finding, problem finding, idea finding, solution finding, and acceptance finding as the core steps for solving problems in a creative manner. Isaksen and colleagues expanded the process stages by adding some, and suggested the creative problem solving procedure in the following order: Constructing opportunities, exploring data, framing problems, generating ideas, developing solutions, and building acceptance. Sawyer similarly proposed an eight-stage model comprising finding and formulating the problem, acquiring knowledge, gathering related information, having time for incubation, generating ideas, combining ideas, selecting ideas, and externalizing the ideas.

Although the number of stages varies according to the models, each similarly includes time for preparation and incubation at the initial stage of the creative process. In relation to introversion, is the creative process, particularly the early stages favorable to introverts? What aspects of introversion contribute to the creative problem solving procedure? Does introversion push one to move towards on the final stage for a creative solution?

The preparation time allows individuals to explore ideas and get information to find and construct problems. The subsequent period of incubation encourages to associate a wide variety of knowledge and information with one another while taking some time off from the routine performance. It facilitates the problem solving process by searching and connecting relevant information and fading out obstructive links that fixate one's minds. In regard to creativity, the benefits of incubation include that it provides individuals with time to relax, shift attention away from the problem, and facilitate to engage in problem-solving activities. Some argue that break and relaxation during the incubation period allows to diffuse one's attention from false information and continue to work on the problem. It also provokes insightful and intuitive thinking (see [Sio and Ormerod, 2009](#)).

Anecdotal evidence supports that creative people (e.g., Charles Darwin, Daniel Libeskind, Franz Kafka, Franz Schubert, Ludwig van Beethoven, Marie Curie, Vincent van Gogh Virginia Woolf, etc.) had a period of incubation as their work habits or during the creative work process. The famous Archimedes' relaxation in the public bath, Charles Darwin's riding in a horse-carriage, and Albert Einstein's playing violin or taking a nap are some examples of incubation activities that urge post-incubation creativity.

Introversion promotes creative thinking from the early stages of the creative process. During these periods, a person is apt to internalize what s/he is interested in, needs time for discovering and finding a problem, and contemplates on generating ideas. Attentional focus is requested to select a few creative ideas out of the many before implementing the selected ones. A broad scope of attention during the preparation and incubation periods helps to make associations among the free floating colliding ideas, while focused attention prompts to make connections among linearly woven ideas. After the incubation period, the narrowly focused attention allows to combine and select some of the ideas crucial for solving the problem. As lonely thinkers like many creative people, introverts are not only fond of securing personal time and space but also good at holding to put devoted efforts into a few areas of their interest and dissipating energy for non-related task. Although they are often regarded as socially isolated and lack compelling leadership, their inclinations to have alone time, internalize problems, and look for clues via attentional focus encourage them to think, imagine, and garner knowledge and information for creative solutions ([Kaufman and Beghetto, 2009](#)).

It seems that the above mentioned introverted personality is instrumental in the initial stages of the creative process that ask for discovering a problem and generating ideas, and the middle stages for converging ideas to find potential solutions. Yet, results are split if introverted people benefit from brainstorming, one of the most used idea generation strategies based on divergent thinking ability. Introverted people are able to produce a quantity of ideas spurred by a wide array of cognitive and emotional activities that occur in the preparation and incubation periods. At the same time, they may want to focus intensively on producing a few quality ideas because they tend to carefully proceed with information and behave prudently in response to the outer stimuli.

The sequential creative process model posits a series of linear steps to reach creative solutions, asking for divergent thinking to convergent thinking abilities at each stage. However, each stage is not fully independent of one another nor strictly formulated but rather embraces both divergent and convergent thinking abilities. What aspects of introversion enhance divergent and/or convergent thinking in the creative process? How does introversion facilitate both types of creative thinking? Neither empirical nor anecdotal evidence has answered these questions explicitly. Further discussions regarding what stage in a certain domain one enters at a certain period of creative development are needed to better understand how introversion contributes to one's creative accomplishment.

Levels of Creativity and Introversion

Creativity starts within the individual who intentionally or unintentionally puts personal meanings to his/her own creative process and in everyday life. Because personal and/or every day creativity is inherent in one's expression of creativity and appears in a wide array of daily activities that one is engaged in, it is not dependent upon domains nor external judgment for creativity. However, when one wants to move beyond the scope of personal creativity, s/he must be able to achieve professional expertise. A professional creator does not have to transform the present domain but has an extensive influence on the domain via his/her achievement.

For individuals with personal but perhaps not professional creativity, introverted tendencies to think internally, obtain personal time and space, work alone, and focus on a few selected creative ideas may help stimulate both a number of and a quality of creative thinking and behaviors in the experience and context of daily life. On a professional level, creative experts spend quality time to

concentrate on and promote their expertise by having at least 10 years of practice. Thus, intentional preparations with alone time are likely to contribute to the attainment of professional creativity and gearing one towards on the next level of creative eminence.

Creativity Today and Introversion: Myths and Facts

Creativity today is conceived of a complex of systems involving individuals, domains, and fields. The system approach encourages to conceptualize creativity based on the manifestation of value-laden products and performance acknowledged by the field and more so by the entire society. The final stages of the creative process consist of verification, acceptance, evaluation, implementation, communication, and/or similar modes of activities. All these procedures facilitate to produce outstanding creative outcomes (i.e., eminent creativity) that are accepted all across the domains to have a significant impact on human life.

Individuals of creative eminence are able to sell their ideas and products to other people higher than their invested time and efforts on the outcomes. They must be good at convincing others, building and expanding their professional networks, and promoting their creative products for the betterment of the society. They are also capable of leading other people and making a difference for the outer world using their widely acclaimed creation.

Introverted people were reported to have lower interpersonal competence and poor communication skills compared to extraverted people. Yet, introverted people do not always lag behind socially. In fact, a number of famous creative people compensate for their introversion by the help of other people and/or their creative work. Some of the creative introverts (e.g., Steve Wozniak, Mark Zuckerberg, Hilary Clinton, Rosa Parks, Eleanor Roosevelt, Moses in the Bible, etc.), for example, demonstrate balanced leadership by placing the opposite partners of extraverted and/or sociable characteristics in their professions. Others also develop interpersonal competence by overcoming social discomfort by pursuing their professional goals with persistence (e.g., Albert Einstein, Charles Darwin, Franz Kafka, Wolfgang Amadeus Mozart, J. K. Rowling, Emma Stone, etc.). Creative achievement at a professional to eminent level is possible if one's introversion moves beyond a personal disposition to become a social attribute. Being socially capable is thus one of the most compelling abilities needed in the final stages of creative development. Because of these credentials, highly achieved creative people look like extraverted more than introverted.

On the other hand, there is a deeply rooted misperception about introversion in the society where the culture of personality leans toward extraversion. Many are aware that today's world favor certain prototypes of personality, such as a left-brained extravert and a socially motivated person. Unfortunately, introverted people are not acclaimed for their dominant personality characteristics. They are generally portrayed as shy, peculiar, lonely, abnormal, timid, nervous, socially maladjusted, problematic, and isolated although these are not the constituents nor qualifications of introversion.

Introverts and extraverts mainly differ in terms of their preferred manners of social interactions. Introverted people like to share their interest areas with a few close friends and avoid conflicts, while extraverted people enjoy socializing with others and dislike being alone. All these matters of difference do not warrant that introverts are interpersonally problematic. Negative stereotypes about introversion and introverts, particular in relation to social skills are rather recent. Many highly creative people are introverted, but they are not always socially incapable. They show the highest creative achievement via efficiently implementing their ideas and selling them well to others and the world.

Conclusion

In the studies of creativity, introversion has not been a major theme nor regarded as a contributing personality to creative achievement. Using the creative process model, this entry discussed how introversion fosters creativity from the beginning stages of creative thinking and from personal to professional levels. A number of highly creative people happen to be introverted across the various domains. What they need for creative accomplishment are personal time and space for thinking and work, a certain degree of solitude, and intensive practices in their areas of creativity before reaching the top. Although it is out of scope to conclude that introversion is a sufficient condition leading to creative achievement, we conjecture that introversion is embedded from the start of creative production.

The Openness to Experience Trait

Personality traits are identifiable as dimensions capturing individual differences in human behavior. Specifically, personality traits organize thoughts, feelings, motivations, and interactions with the environment in defined patterns, which are consistently displayed over time and that highly influence the individual's values, expectations, behaviors, and self-perceptions. Among the fundamental dimensions of personality, Openness to Experience refers to a continuum of individual differences in the desire for and processing of experience, based on the depth and breadth of consciousness, and leading to a constant drive toward exploration and enlarging exposure to reality (McCrae and Costa, 1997). Individuals high in Openness to Experience are described as original, imaginative, unconventional, curious, intellectual, and creative. The main theoretical framework under which this trait is conceptualized is the Big-Five model, which identifies five fundamental dimensions in personality: Extraversion, Agreeableness, Conscientiousness, Emotional Stability (vs. Neuroticism), and Openness to Experience.

Labeling Openness (to Experience): Underlying Factors

Openness to Experience captures a broad and complex ensemble of characteristics that render it very difficult to grasp which arguably makes it the most controversial of the personality traits. As a symptom of this complexity, this personality dimension took on many different names over time, among them Culture, Cultured, Intellect, Openness, and Openness to Experience.

The label Culture/Cultured was used to capture in this trait facets such as intellectual, curious, imaginative and polished, suggesting that these aspects of personality could be the result of education. According to this label, education would act on personality through exposure to a broad range of ideas, active engagement in arts and science, and aversion toward accepted norms and values. However, even if education (especially a liberal education) is congenial to individuals who are high in Openness, research has proved that education plays only a minor role in the development of this personality trait. This evidence, along with the fact that the Culture label is not apt to identify a clear factor in several analyses, led to abandoning this term.

A second label that has had considerable diffusion is Intellect, which derives from the lexical tradition and identifies the tendency toward reasoning, building new knowledge, and understanding. In fact, the engagement of open people in a variety of experiences along with their tendency to spend time in activities requiring/inducing acquisition of information (such as reading all genres of literature) leads them to build a wider general knowledge. As a consequence, individuals high in Openness are characterized by higher crystallized intelligence. Even if initially Intellect was proposed as an alternative labeling to Openness to Experience, the current research is providing evidence of the fact that Openness and Intellect are distinct but equally central aspects of this trait (DeYoung et al., 2012). The twofold nature of the Openness to Experience trait can be therefore captured by its two main factors: Openness (also referred to as the Experiencing factor) and Intellect. The Openness factor has been associated with the appreciation for aesthetics, with deep experiencing of sensations and feelings, with absorption in fantasy and imagination. The Intellect factor is

associated with a tendency toward broad abstraction, intellectualism, enjoyment of philosophy, and engagement with abstract and semantic information.

In addition, a third factor was recently proposed, Open-mindedness captures non-traditionalism, seeking variety, and acceptance of diversity. While the Openness/Intellect factors reflect the individual's vision of the world (physical or intellectual, respectively), Open-Mindedness can be seen as the breadth of the world's impact on the individual. This subdivision into two or more constitutional factors produces a call for further research to achieve a more precise and distinctive structure and terminology. Irrespective of the adopted subdivision of Openness to Experience into factors, usually this trait is explored as a global dimension of the Big-Five model, in order to capture its complex phenomenological essence. When this does not produce ambiguity, the label can be shortened to Openness trait (not to be confused with the Openness factor). Indeed, Openness trait and Openness to Experience trait can be found interchangeably in the literature, and we adopt the short form in the following. (See Personality: Big-Five Personality Characteristics)

Measuring Openness in the Questionnaire Tradition

The Openness trait is defined in the questionnaire tradition as a set of lower order facets, which depend on the selected measurement instrument. While there is substantial agreement on the centrality of some facets (e.g., aestheticism), others tend to appear in a scattered manner.

A recent systematization of the facets defining the Openness trait has been provided by sorting and meta-analyzing eighty-five scales (Connelly, Ones, Davies, & Birkland, 2014). Eleven facets emerged from this analysis to be theoretically and empirically related to Openness: Aestheticism, Autonomy, Fantasy, Innovation, Introspection, Nontraditionality, Openness to Emotions, Openness to Sensations, Thrill-seeking, Tolerance, and Variety-seeking. Only four facets emerged however to be pure and related uniquely to this trait: Aestheticism, Openness to Sensations, Nontraditionality, and Introspection.

It is important to highlight that normally Openness is measured with questionnaires assessing all five personality traits in the Big-Five model. However, specific instruments have been developed to measure this specific trait independently, such as the Openness to Experience Inventory (Woo et al., 2014) which measures six facets (Aesthetics, Curiosity, Depth, Intellectual efficiency, and Tolerance) organized in two general factors, Culture (i.e., Experiencing) and Creative intellect (i.e., Intellect).

Openness and Creativity

The personality of highly creative individuals is often described as imaginative, adventurous, bored by routine, incredibly curious, able to see possibilities that others miss. As mentioned before, these characteristics are all elements constituting the archetype of those individuals observed and considered to define the Openness trait. Indeed, since the start of the theoretical discussion on Openness, this trait has been intrinsically related to creative behavior. In fact, the terms "creativity" or "creative" can be found in the wording of several items in the measurement scales for this trait. Not surprisingly, reviews and meta-analyses have identified Openness as the personality trait more strictly associated with creativity within the Big-Five model (Feist, 1998; Puryear et al., 2017).

Moreover, recent data showed that Openness is one of the most important variables defining lifetime creative achievement, i.e., frequency of episodes of creative success in the course of one's lifetime. Specifically, Jauk et al. (2014) demonstrated that Openness together with the individual's creative potential and intelligence predict creative achievement, possibly through a reduction in the behavioral threshold to engage in creative activities, and the consequent increase in success rate. Openness would then interact with the individual's intelligence level, with results showing that only people with intelligence above a threshold and performing several creative activities, thanks to their Openness, can reach high creative achievement levels.

Openness within Different Conceptualizations of Creativity

Given the fundamental relationship between Openness and creativity, it must be stated that its magnitude varies across different possible conceptualizations and operationalizations of the creativity construct. A sharp distinction exists between the study of creative potential (the capacities and predispositions toward possible future creative success) and that of creative achievement (the track-record of creative success in a lifetime). Typical measures of an individual's creative potential include divergent thinking tasks, whereby indexes such as originality, fluency, flexibility, or elaboration in the production of alternative ideas can be derived.

Considering creative achievement in a lifetime, measurement instruments such as the Creativity Activity and Accomplishment Check list (CAAC) derived from the Creative Behavior Inventory (CBI; Hocevar, 1979), or the Creative Achievement Questionnaire (CAQ; Carson, Peterson, & Higgins, 2005) are used. These instruments, referring to creative success in domain specific and/or everyday activities, are self-report check lists on the quantity (number or frequency) and quality of creative efforts and their recognition. The relationship between Openness and creative potential or creative achievement is also influenced by the person(s) estimating the creative products: self-assessed versus others-assessed approaches may lead to quite different results. Exemplary of the first category is the self-report method, of the second the Consensual Assessment Technique.

Creative Potential Versus Creative Achievement Measures

As mentioned above, divergent thinking tasks are the most accepted measurement instruments that gauge an individual's creative potential and in particular his/her ideational ability. Originality of the responses and fluency are the most adopted indexes in the quantification of divergent thinking performance. Independently of the adopted index, research showed a consistent positive association between Openness and divergent thinking performance. A systematic review by Ref. [Puryear et al. \(2017\)](#) showed that when the relationship between personality and creative potential versus creative achievement is explored, Openness emerges as the most strongly and positively correlated trait with both measures.

However, a diversified influence of Openness on the two types of measures appears to emerge: when variance is explored, Openness explained creative achievement measures at more than twice the rate of creative potential measures. This result underlines the importance of the type of conceptualization and related operationalization of the creativity construct in the analysis of the creativity–Openness link. In particular, it appears that the Openness trait plays a more important role in real-life creative achievements than in divergent thinking tests.

Self-Assessed Versus Others-Assessed Measures

Another key element affecting the relationship between Openness and creativity is the adoption of either self-assessed or others-assessed approaches. In general, Openness emerged as the best predictor within the Big-Five model of both self-assessed and others-assessed creative performance. However, since self-assessed measures are person-centered, just as personality inventories are, one could suppose the existence of a stronger relationship between self-assessed rather than others-assessed measures of creativity and personality, and in particular Openness.

Experimental data support this expectation: as reported in the meta-analysis by Ref. [Puryear et al. \(2017\)](#), Openness explained almost three times the variance of self-assessed creative performance as opposed to others-assessed results. This result should be taken with caution, as it may emerge from a partial overlap between the self-assessment of Openness and the self-report measure of creativity. Indeed, items in the Openness profilers contain terms such as creativity, imagination, ideas, etc. Also, the higher correlation emerging between self-assessed measures of Openness and creativity may be imputed to the self-report modality itself, which in a fundamental way relies on the individual's sensitivity to appreciate characteristics and idiosyncrasies in his/her own behavior. In other words, a common variance in these self-assessed measures could be generated via the individual's self-image or personal identity, which in turn is related to the concept of creative self-beliefs.

Creative Self-Beliefs

Self-beliefs are intended as individuals' convictions about their own abilities and potential. Three forms of creative self-beliefs have been explored in creativity studies: self-rated creativity (individuals' assessment of their creative abilities or potential), creative self-efficacy (individuals' beliefs in their own capacity to manage and sustain creative challenges), and creative personal identity (deeply rooted into the relevance assigned to creativity in one's self-image).

Openness has been shown to be significantly associated to all of these forms. A distinction has been proposed in the literature between core personality traits and surface self-concept characteristics: while the former would be rooted in genetic characteristics and as such less sensitive to culture and environment, the latter would be more exposed to context-related influences. In this view, personality traits are considered basic tendencies, while surface self-concepts are characteristic adaptations. This distinction is necessary since the apparent strong association between Openness and all forms of creative self-beliefs called into question whether measures of creative self-beliefs are actually able to measure anything else but Openness itself. However, a recent meta-analysis by [Karwowski and Lebuda \(2016\)](#) showed that the association between Openness and creative self-beliefs is indeed positive and consistent across studies, but perhaps not as strong as previous research seemed to suggest.

The strength of this relationship is significantly affected by the adopted type of self-concept measures, with stronger associations emerging when using domain-general versus domain-specific measures of creative self-beliefs. Moreover, the choice of the Openness measurement tool has an impact: shorter scales lead to higher correlations than longer scales. These results seem to confirm the relative independence of the two types of constructs. At any rate, these findings call for further study about the effective relationship between traits and self-beliefs, and in particular whether the Openness trait could be considered the cause of the much more malleable creative self-beliefs.

Explanatory Mechanisms in the Relation Between Openness and Creativity

Openness is therefore the personality dimension most deeply interconnected with the creativity construct, and this trait can be observed through a variety of experience enlarging behaviors. Recent research has therefore dedicated attention to understanding whether the relationship between Openness and creativity can be explained through specific behavioral mechanisms, which might act as a bridge between this personality trait and creative performance. The intention is to pass from the study of Openness as a generic tendency to the analysis of specific mechanisms related to Openness, with the purpose of identifying specific behavioral/physiological vehicles linking this trait to creativity. This research field has produced numerous explicatory models, suggesting mediator and/or moderator roles for defined behavioral or cerebral mechanisms in the association between Openness and creativity.

Cognitive and Cerebral Mechanisms

The main cognitive characteristic of individuals high in Openness is the tendency to direct their attention to a variety of knowledge domains and cultures, which can be identified as breadth of interest. When involved in a specific task, they possess an ability to notice and give attention to information that is not considered mainstream, but that vice versa could be defined as unconventional, or sometimes even irrelevant.

Batey and Furnham (2006) hypothesized that the relationship between Openness and creativity could be due to a lower tendency toward filtering out irrelevant information, which can then enter into the creative thinking process. According to this hypothesis, people high in Openness would have less selective attentive filters, letting in a larger portion of reality in comparison to closed-minded people, and this would turn out to be instrumental in enabling a larger pool of associations during ideation.

Indeed, the relationship between attention and creativity is a classic theme in creativity studies with a cognitive approach. Past results showed for instance that breadth of attention is a main correlate of creative performance. Individuals with wide attentive focus allow inputs from irrelevant stimuli because their attentive filters are not selective enough to prevent the inclusion of unwanted information into the thinking process (Necka, 1999). (See Breadth of Attention)

Similar results emerged in the study of the association between latent inhibition and Openness, showing that individuals with higher Openness levels are characterized by lower inhibition scores, testifying easier access to complexity, i.e., a wider span of information. Starting from this scientific evidence, a recent study explored whether attentive processing could act as a moderator in the relationship between Openness and creativity (Agnoli et al., 2015). Identifying as *irrelevance processing* the elaboration of apparently irrelevant information, and exploiting an eye-tracking set-up, it was possible to show that irrelevance processing allows those people high in Openness to reach superior creativity levels as measured by both their performance in a divergent thinking task and by their self-report measure of creative achievement. Specifically, the statistical interaction between irrelevance processing and Openness in influencing creativity outcomes was shown, confirming that attentive processing is a central cognitive mechanism in the relationship between Openness and creativity. These results seem to suggest that the relation between a core personality trait, such as Openness, and creativity can at least partially be conveyed through a specific attentive mechanism, i.e., irrelevance processing.

In a search for neural correlates underlying the Openness-creativity relation, a neurophysiological study explored the anatomy of specific brain structures as a possible explanatory mechanism (Li et al. 2015). This study showed that the regional gray matter volumes (rGMVs) of specific brain regions were associated with trait creativity. In particular, the rGMV of the right posterior middle temporal gyrus (pMTG) was positively correlated with individual trait creativity. It was suggested that the contribution to creativity of large rGMV in this region can be explained by the semantic processing functions typically associated to the lateral temporal cortex: semantic processing of metaphors, conceptual integration and comprehension, and novel associations.

Interestingly, this study also showed that Openness could act as a mediator in the association between the rGMV in pMTG and trait creativity. Openness emerged indeed to be related to both the rGMV in pMTG and trait creativity, and to reduce their association via a partial mediation. Lin et al. (2015) proposed that this mediation role could be related to the Openness-enabled induction in the right pMTG of specific patterns of cognitive processing associated to imagination, curiosity, and fantasy. Openness would therefore stimulate the cognitive functions related to the pMTG, which in turn are strictly related to creative performance.

Emotional and Motivational Mechanisms

The creative process is permeated by emotions (Agnoli and Corazza, 2019). Emotions emerging from failures or negative feedback, as well as from success, can give specific directions to the process, increasing or decreasing for instance the willingness to engage in further creative activities. The ability to maintain high intrinsic motivation, i.e., an enjoyment in the activity, is believed to be essential to succeed despite negative external evaluations, making the difference between giving up and persisting in the creative process. In this framework, emotional intelligence plays a relevant role, starting from the ability to self-monitor one's emotional state. Research indicated open people were more prone to pay attention to inner feelings. Moreover, Openness is associated to higher levels of intrinsic motivation. Given this evidence, the role of emotion and motivation has been explored as a possible further exploratory mechanism in the relationship between Openness and creativity.

Ivcevic and Brackett (2015) found an interaction between Openness, which they intended as a personality disposition toward creativity, and emotion regulation abilities in predicting students' creativity as assessed through nominations by peers. While emotions regulation *per se* does not appear to help people in being more creative, it does seem that this ability can enable the reach for higher creativity levels in open individuals. Since people high in Openness have a dispositional preference for new ideas, and are in general more willing to take risks in order to realize these ideas, they are more likely to be exposed to the emotions permeating a creative process. Emotional regulation emerged therefore as an important interactive variable in the management of emotions by individuals high in Openness, including feelings associated to failures, poor external evaluations of one's work, or the elation emerging from great success.

Another fundamental component that drives the entire creative process is motivation. Motivation is necessary to activate the cognitive and attitudinal resources that allow individuals to face the challenges of the creative process. Most creativity researchers agree in particular on the importance of intrinsic motivation, which has been shown to interact and relate to the Openness trait in predicting creative performance and achievement. Prabhu et al. (2008) for example demonstrated that intrinsic motivation partially mediated the relationship between Openness and creative self-perception: open individuals score higher in their self-evaluation of creative abilities due to their characteristic of being intrinsically motivated toward creative activities. These findings were also

supported in a study by [Tan et al. \(2019\)](#) who showed that the Openness–creativity relationship is mediated by the connection between intrinsic motivation and engagement in creativity-related activities. In other words, individuals who are high in Openness tend to have higher scores in creativity self-evaluation; thanks to their increased intrinsic motivation which in turn increases their engagement in creative activities.

Openness is therefore very useful but not sufficient for a highly creative self-identity; according to these findings, individuals must also engage in creative activities for the sake of personal satisfaction, be ready to invest significant resources and take risks. The role of intrinsic motivation emerged as central in the explanation of the Openness–creativity relationship not only when creative self-perceptions are explored, but also when creative achievement is used as a criterion. In the study by [Agnoli et al. \(2018\)](#), intrinsic motivation interacted with Openness in the explanation of students' creative achievement both inside and outside of the school environment. These results interestingly show that only in the presence of a sufficient level of Openness does intrinsic motivation act as a significant predictor of creative achievement in the considered environments. Irrespective of the context, therefore, people should be open-minded enough to use their intrinsic motivational tendencies to achieve creative success.

Socio-Cultural Influences on Openness and Creativity

The above discussion has been laid out taking the point of view of a single individual, endowed with an inventory of personality traits, and engaged in creative activities, with little concern for the surrounding socio-cultural environment. This approach is definitely reasonable and scientifically sound, given the focus on a specific personality trait and its influence on an individual's creative potential and achievements.

On the other hand, a systemic view on the creativity construct requires that the individual's experience and characteristics are embedded in an environment, which does play a fundamental role in providing opportunities, pressure, feedback, challenges, and so on. In this view, personality traits do not predetermine one's experience, but they interact with the relevant social and cultural situation in order to generate a dialogue out of which a unique experience is instantiated. This reasoning is in line with a socio-cultural manifesto for creativity ([Glaveanu et al., 2019](#)), according to which creativity is a culturally mediated action, and the role of personality characteristics should therefore be mapped onto this systemic view of a complex construct. Questions addressed here include the following: What are the cultural influences on the Big-Five model of personality, and in particular on the Openness trait? What is the influence of cultural characteristics such as collectivism and individualism on the creative construct and its relationship with the Openness trait? Considering the social organization of cultural activities into knowledge domains, in particular distinguishing between artists and scientists, should Openness effects be considered as domain general or domain specific?

Cultural Influences on the Big-Five Model of Personality

It is important to start this discussion by stating immediately that a large body of scientific literature appears to confirm the Big-Five model emergence in various cultures, the observation of similar patterns of developmental personality change in adulthood, as well as the possibility to predict patterns of acculturation effects on personality for immigrants across different cultural milieus. This amount of evidence justifies the hypothesis that there exists a significant biological foundation underlying the definition of the core personality traits. ([McCrae and Costa, 1997](#)).

It is then possible to perform studies that try to correlate cultural values and models of personality traits across cultures, an exercise notably carried out by [Hofstede and McCrae \(2004\)](#), who compared different hypotheses and conclusions based on the same data but taking the points of view, respectively, of cultural psychology or of the psychology of personality. In this study, Openness turned out to be connected to various dimensions of culture, such as for example power distance (the extent to which less powerful members of society accept and expect that power is distributed unequally): individuals living in low-power distance countries tended to score higher in Openness than in high power distance countries.

However, caution should be exerted in claiming universality of Big-Five personality factors across cultures; indeed, out of the five factors, Openness appears to be perhaps the most problematic in cross-cultural application ([Triandis and Suh, 2002](#)). As an example, administration of personality profilers in Hong Kong and China by [Cheung and Leung \(1998\)](#) led to confirm Neuroticism, Extraversion, Agreeableness, and Conscientiousness factors, with the sole exception of Openness. There could be many reasons behind this result: poor quality in item translation; lack of relevance of an item in a cultural milieu; response style differences, including different social desirability standards; test format problems; trait-level and trait-structure differences. This means that even if the Big-Five model does not emerge in a specific culture, this evidence is not sufficient to conclude that it is not applicable: this apparent difficulty in falsifying the Big-Five theoretical framework is a clear hurdle from the scientific point of view, to be addressed by future research.

Individualism and Collectivism: Influence on Openness and Creativity

In order to investigate those macroscopic aspects that might have an influence on the distribution in a population of the Openness trait, it is useful to define two opposing poles in the characterization of cultural trends: individualism versus collectivism. Whereas in a collectivist culture individuals have close mutual links and see themselves as part of one or more social structures

(family, organization, and nation), members of an individualist society see themselves as independent entities who rely on themselves for success and dignity.

A further specification, which is in fact orthogonal to the individualism–collectivism axis, is that of vertical versus horizontal societal structure: a vertical structure implies large power distance, strong hierarchies which are difficult to climb, whereas when horizontal values prevail the structure is flat and there is great emphasis on equality and fairness. These distinctions are significant in terms of how people see society around them and themselves in the environment. Persons living in a collectivist society, more vertical than horizontal, see the environment as stable and themselves as malleable, to fit in the collective. In these conditions, personality traits and their influence on behavior emerge with more difficulty. Openness is not as powerful as a predictor for creative performance. Vice versa, people in an individualist milieu, more horizontal than vertical, see themselves as having stable attitudes, personalities, and rights, and they may act to change the environment. It is here that personality traits emerge in all their relevance, and particularly the relationship between Openness and creativity.

Since the Big-Five model was born in the milieu of Western culture, which is prevalently individualistic, it is reasonable to expect that there may be differences when its application is proposed to the more collectivist-oriented Eastern countries (Triandis and Suh, 2002). At the same time, Western culture is also the environment in which creativity studies have initially been developed, and several notions in creativity studies have been questioned regarding their cross-cultural applicability, starting from the definition of creativity itself. All in all, it is safe to state that socio-cultural aspects of Openness, creativity, and their interrelationship deserve further scientific investigation.

Domain Generality for Openness in Creativity: Artists Versus Scientists

Within every culture there are significant distinctions in terms of domains of knowledge, and the statistical distribution of individual differences might be affected by the fact that one is belonging to a specific knowledge domain. The question here is whether the Openness personality trait and its relationship to creativity can be considered to be a domain-general item or conversely if it should be treated under the light of domain-specific distinctions. Clearly, the outcomes of this analysis depend also on the semantic distance between the knowledge domains under study.

Two domains that are typically considered to be sufficiently distinguishable are those of sciences and the arts, even though it would be incorrect to build a sharp dichotomy between these two fields. In order to come to conclusions with sufficient validity, it is useful to resort to meta-analyses of personality studies in the domains of scientific and artistic creativity, such as that conducted by Ref. Feist (1998). There, lifetime creative achievement and the Big-Five model were used to perform three orders of comparison: scientists versus nonscientists, creative versus less creative scientists, and artists versus nonartists. The most important result out of this meta-analysis is that, irrespective of measurement approaches and taxonomies used for personality and creativity, creative individuals in both domains were characterized by high levels of the Openness trait, with a very significant effect size. In other words, these results appear to suggest that Openness can be considered to be a domain-general requirement for creative performance and achievement, at least in both sciences and the arts.

A Prime Example of Openness: Leonardo da Vinci

It can be argued that polymathy is perhaps the most evident behavioral sign of high levels of Openness. R. Root-Bernstein & M. Root-Bernstein (2004) showed that polymathy is not an isolated feature but a common characteristic of highly successful creative achievers, such as Nobel Prize winners. This discussion of the Openness trait is therefore concluded by describing in short the characteristics of the person that can be argued to have been the greatest polymath, as well as creative genius: Leonardo da Vinci. Notably, Leonardo is also the first example brought up by Ref. McCrae and Costa (1997) of a person possessing the archetypical set of mental, emotional, and attitudinal traits that characterize people that are high in Openness, justifying the necessity for this factor in a model of personality.

Leonardo was born in Vinci on the 15th of April of 1452, the illegitimate son of a notary and a peasant woman. Had Leonardo been a legitimate son, he would have simply become a notary, a closed destiny for what might have become a closed mind. He spent his early childhood freely roaming in the Tuscan countryside, open to wild experiences under the mild guidance of his uncle Francesco, a modest philosopher who invested a long time in discussing nature with the young Leonardo, teaching him to appreciate both its beauty and its perfect equilibrium. It can be argued that these early years were fundamental in shaping the vast curiosity and Openness to Experience of Leonardo.

When he reached the age of 10, Leonardo moved to Florence and at 14 years old he entered the Bottega del Verrocchio, a thriving workshop at the peak of Renaissance times, in the good company of great artists-to-be such as Botticelli and Il Perugino. There, Leonardo was engaged in all kinds of activity, from painting to sculpture, from drawing to solving engineering problems, from manufacturing objects to discussing the principles of life. Without formal education, Leonardo defined himself “homo senza lettere,” an unscholarly man, but there could have been no better training if the goal was that of becoming a polymath.

Working in Florence, Milan, Mantova, Venice, Rome, and finally Amboise, Leonardo never stopped enlarging the breadth of his interests, until the very end of his life, and this relentless cross-domain activity led him to achieve world’s highest creative success in nearly 20 different disciplines: painting, drawing, sculpture, music, scenography, special effects design, cartoon design, prose writing, anatomy, optometry, optics, botany, geology, geometry, engineering invention, aerospace engineering, mechanical

engineering, hydraulic engineering, robotics engineering, military engineering, civil engineering, architecture, city planning, cooking, and nutrition sciences. Leonardo died on May 2, 1519, i.e., approximately five hundred years before the time of writing this encyclopedia, and he remains the unmatched exemplary figure exhibiting the highest level of Openness and creativity ever achieved.

Creativity involves the generation of novel and useful products, ideas or procedures. Creativity has long been inherently associated with risk reflecting the idea that risk-taking is integral to creativity or that creative people are risk takers (Prabhu, 2011, p. 319). Accurately speaking, it seems more appropriate to treat creativity and risk-taking as two independent but relevant constructs, wherein risk-taking can be considered a key personality characteristic of creative individuals (e.g., Feist, 1998).

Risk and Risk-Taking

Risk, a key component of uncertainty, often involves objective risk as estimated by “experts”, and subjective risk as estimated and experienced by everyone. The distinction between subjective and objective risk can be illustrated by this example—if a particular mushroom dish is believed to be healthy, then the objective risk of it being poisonous will not be experienced as a (subjective) risk until the body responds to the poison; if, however, an individual subjectively believes that there is a risk involved in an action, such as eating a poisonous mushroom, then the objective riskiness of that action becomes unimportant for determining whether the person is a risk-taker (Trimpop, 1994). That is, subjective risk is more important than objective risk in determining whether a person is a risk-taker. Only if an action is considered or known to bear negative consequences, can it be experienced as a risk. Yates (1990, 1992) specified three key components of risk, as follows: (1) the involvement of loss; (2) the significance of the loss—the perceived utility of the loss outcome or the weighted size of credible loss; (3) the uncertainty linked to the loss—the probability of loss (as expected) and the variance of the probability distribution over the probability of all potential consequences.

The concept of risk-taking propensity has important implications for theoretical research on risk-taking and risk activities, and for giving practical insights into the motives underlying individual-level choices about engaging in risky behavior. Risk-taking is any consciously or unconsciously controlled action taken where there is perceived uncertainty about its outcome and/or the possible benefits or costs to the physical, economic or psycho-social well-being of oneself or others. Although risk-taking can be situational and dispositional, the majority of existing studies imply that risk-taking is (pre-)dispositional as opposed to situational. Importantly, risk-taking was traditionally considered to be a single personality trait, similar to impulsiveness (Eysenck and Eysenck, 1977). However, this view is gradually being replaced through the recognition of distinct risk-taking components highlighting its multi-dimensional and domain-specific nature. Accordingly, risk-takers are individuals who prefer riskiness and to take risky actions where the consequences and/or probabilities of outcomes are entirely unknown or only partially known. Moreover, this preference goes beyond a single, specific situation, showing instead considerable cross-situational and even cross-domain consistency. That is to say, risk-takers tend to prefer risky actions or choices in a variety of different situations.

As a personality trait, dispositional risk-taking, also termed risk-taking propensity, could be regarded as a facet of extraversion as identified by the Big-Five personality theory. As a multi-dimensional construct, it is influenced by a considerable number of traits and emotions: positively by such traits as extraversion and openness, and negatively by neuroticism, agreeableness and conscientiousness. In addition, individual differences in negative affect or emotions, such as anxiety or worry, have a negative impact on risky decision-making, making an individual more risk-averse. In sum, risk-taking is a relatively stable, multidimensional personality trait or disposition that can be generalized from an individual’s behavior choices or attitudes toward riskiness in one situation to many situations, or at least to the majority of situations within the same domain.

Risk-Taking Calculation and Assessment

The appropriate measurement of risk-taking has long been a subject of debate among scholars in personality psychology, management science, decision science, economics, and other fields, reflecting the perceived theoretical and practical significance of this construct. Risk-taking varies according to the individual; that is, everyone has a different level of risk-taking, influenced by a number of factors. Understanding the determinants of risk-taking is not only of theoretical interest but can also provide practical insights for financial regulatory requirements. Studies indicated that individual risk-taking is influenced by previously experienced personal outcomes, gender, age and outcome feedback, as well as an individual's risk attitude and risk perception. Risk perception is an individual's estimation of the risk inherent in a situation, and commonly involves the processes of objective computation and subjective estimation of risk. Accordingly, risk perception is essentially a subjective process, in which individuals assign different riskiness weight to the same (objective) event. Some people may have a relatively positive attitude toward risk while others may have a negative perception. According to classic portfolio theory (Markowitz, 1952), a person's risk-taking depends on their risk attitude and estimates of the expected return (expected utility) and volatility (variance) of a business (i.e., the probability of the loss of the investment). Ultimately, risk taking is calculated by the curvature of the investor's utility function, as follows (see Weber et al., 2012):

$$\text{Risk taking} = f(\text{expected return, risk, risk attitude})$$

In this equation, risk attitude is the trade-off between risk (the probability of such a gain) and expected utility (return), and is directly assessed by asking the investor. To measure an individual's risk-taking, numerous studies have developed many instruments and paper-and-pencil scales. In the following section, four commonly used measures for assessing individual risk-taking are introduced.

Risk Preference Index (RPI)

The RPI, developed by Hsee and Weber (1997, 1999) is a commonly used measure for assessing individuals' preferred level of risk-taking, with good cross-national validity. An RPI score is computed from responses to a set of 14 questions, one-half of which relate to a gain situation, the other half to a loss situation. Respondents are required to rate their level of risk-taking for each situational question on a Likert scale ranging from 1 (most risk-averse) to 8 (most risk-seeking). In the gain situations, if a participant chooses the non-risky option in all seven questions, her/his RPI equals 1 (most risk-averse). If she/he chooses the risky option in all seven questions, her/his RPI equals 8 (most risk-seeking).

Domain-Specific Risk-Taking Scale (DOSPERT)

The DOSPERT was developed as a domain-specific measure of individual risk-taking, in order to examine situations in which the same person displays different risk-taking attitudes in distinct domains—for example, one in sport and another in finance. Popularized by Kogan and Wallach (1964), it has been used extensively to identify the general risk-taking propensity of individuals. It is a standardized questionnaire consisting of 30 questions across five different domains of risky behaviors (Ethical, Financial, Health/Safety, Recreational, and Social) (Blais and Weber, 2006). Each domain typically contains six items, and individuals are required to rate the likelihood of engaging in risky activities on a seven-point Likert scale ranging from "extremely likely" to "not at all likely" (different versions of this scale have different scoring methods, e.g., some of them use a five-point Likert scale (Kamalanabhan et al., 2000)). Higher scores on the scale suggest greater likelihood of engaging in risk-taking. Sample items include: "Passing off somebody else's work as your own" (ethical), "Disagreeing with an authority figure on a major issue" (social), "Bungee jumping off a tall bridge" (recreational), "Driving a car without wearing a seat belt" (health/safety), and "Betting a day's income at a high-stake poker game" (financial). In accordance with the risk-return and expected utility framework, DOSPERT also contains simple measures of risk perception (from "extremely risky" to "not at all") and expected benefits (from "substantial benefits" to "no benefits at all") on a seven-point Likert scale. "Risk perception" responses are seen as reflecting an individual's gut-level assessment of risk, whereas "expected benefits" responses measure the degree of benefit a person stands to gain from such "risky activities" (Tyagi et al., 2017).

Choice Dilemmas Questionnaires (CDQ)

The CDQ, developed by Kogan and Wallach (1964), encompasses 12 vignettes depicting a daily situation in which a dilemma choice must be made between a desirable "bird in the bush" and an even more attractive "bird in the hand." The questions are selected from different domains of everyday life, and then combined into a single score that purportedly reflects an individual's level of risk-taking. For instance, in a scenario in which participants are asked to decide whether they would leave a stable job to take a better-paying job at a company with uncertain prospects, they must indicate what probability of success would be sufficient to make them choose the risky alternative—e.g. 1 in 10, 3 in 10, 5 in 10, and so forth. A low score indicates risk-taking, while a high score implies risk aversion or risk avoidance. This instrument has been used extensively in a variety of studies examining risk-taking in groups or individuals. As for its reliability, Kogan and Wallach (1964) reported an internal consistency of 0.62 for

females and 0.53 for males. Although these indicators are not very high, this questionnaire remains the most frequently used measure of risk-taking.

Balloon Analogue Risk Task (BART)

The BART, developed by [Lejuez et al. \(2002\)](#), is a relatively new, computerized, laboratory-based measure with high ecological validity, that assesses actual risk-taking. This measure is very similar to real-world risky behavior, in which individuals can be rewarded up to the point at which they experience a reversal as a result of an unknown risk. In this task, a series of computer-animated balloons are presented one at a time, which participants are asked to inflate by repeatedly pressing a “pump” button to administer puffs of air. As participants click this button and the simulated balloon increases in size, they earn increasing amounts of money (which accrues in a temporary bank). Each balloon can burst at any moment, according to an array of N numbers. Participants must decide how often to keep pumping and risk the balloon bursting, or stop pumping the balloon at any point during the trial. If they do so before the balloon bursts, all the points or money she/he has accumulated in her/his temporary account is transferred to a permanent account (by pressing the money collection button); however, if the balloon bursts (with a “pop” sound), all the points accumulated in the temporary account are lost. After each trial, a new balloon appears, until the designated number of balloons (trials) have been completed. Participants are not told about the likelihood of the balloon bursting ([Sela et al., 2012](#)). Once the entire test is completed, several indicators can be extracted, including the total number of exploded and unexploded balloons, the distribution of unexploded balloons, and the number of times of clicking the balloon immediately following a burst balloon. Previous studies demonstrated that all these indicators are closely associated with risk-taking and the test has been validated as reflecting dispositional risk-taking.

Other measures, including The Benthin Risk Perception Measure (BRPM), The Impulsiveness Questionnaire, The Game of Dice Test (GDT), The Iowa Gambling Task (IGT), The Delaying Discounting test (DDT), the Roulette Betting Task (RBT), and the Cambridge Gambling Test (CGT) were used in previous studies to measure individual risk-taking. The four instruments listed above each have their own advantages and can be used selectively in different studies according to research approaches and requirements. For example, the BART provides data on individual general risk-taking with high ecological validity, whereas the DOSPERT can assess an individual's domain-specific risk-taking.

The Roles of Risk-Taking in Creativity

The role of risk-taking in creativity is an issue of growing interest. Traditionally, risk-taking is seen as being integral to creativity. Consequently, some well-known theories and measures of creativity included a risk-taking component in their construct. For example, the Williams Test of Creative Propensity (1980) consists of a subscale with risk-taking as a personality trait or disposition.

Taking sensible risks is considered a prerequisite for triggering or nurturing an individual's creativity according to the investment theory of creativity ([Sternberg and Lubart, 1992](#)). However, several recent studies have refuted such a simple association between risk-taking and creativity. Generally speaking, the development of novel ideas is risky because new ideas imply violating or changing the previously established order and associations. A newly created thing or novel idea may be original, however, its appropriateness or usefulness is less salient and may be difficult to determine. Many creative ideas may be rejected because of they are perceived as irrelevant or impractical. Often ideas which turn out to be extremely important are rejected because they are so different. This tendency is especially true when individuals experience uncertainty-related risk ([Mueller et al., 2012](#)).

The individual creator in the arts must grapple with the risk of limited earnings or poverty while they learn their craft with no guarantee they will ever make a living. The mature working artist has to deal with taking appropriate risks in the market including trying new ideas. Startup companies take big risks since most of them fail while successful companies constantly face the need to innovate.

The empirical data available on risk-taking in creativity is limited and still open to debate. Creativity is not an entity but a complex construct encompassing multiple heterogeneous components, such as divergent thinking and convergent thinking. In two studies, [Tyagi et al. \(2017\)](#) presented a diverse range of creativity measures combined with two risk-taking scales—the DOSPERT and Roulette Betting task—individually to 64 and 417 volunteers respectively. Their results showed that creativity assessed using the Creative Achievement Questionnaire (CAQ), Runco's Ideational Behavioral Scale (RIBSs), and Gough's Creative Personality Scale (CPS) was associated with high risk-taking propensity in the social domain only. Neither performance on the thinking measure (i.e., alternate uses task, AUT) nor that on the compound remote associate task was related to risk-taking, suggesting that while it may be appropriate to treat risk-taking as a trait, at least in the social domain, it is not homogeneously associated with creativity. Moreover, the likelihood of risk-taking in the social domain only was the strongest predictor of creative personality and ideation scores but did not predict other measures of creativity.

Another study conducted in a Chinese cultural setting—in which individuals are considered to be less risk-averse, especially to material or financial risks—found that risk-taking measured using the RPI indicated that dispositional risk-taking was positively correlated with divergent thinking and negatively correlated with convergent thinking ([Shen, Hommel, Yuan, Liu, & Zhang, 2018](#)). For another, risk-taking is a construct of multidimensional nature, considering risk-taking not only as disposition or personality trait, or a situational facilitator motivating an individual's creative effort, but also as a state construct—willingness-to-take-risks

(WTR)—conceptualized as an extension of Sitkin and Pablo's (1992) treatment of risk-taking propensity. In contrast to risk-taking propensity, WTR is a state (rather than a disposition or tendency), is context-specific (applying to the specific case of creative behaviors as opposed to decision-making in general), and includes the specific consideration of the possibility of potential negative outcomes. Many factors might influence the association between risk-taking and creativity so there may be no simple or homogeneous role of risk-taking in such complex activities or creative behaviors.

Conclusion

A review of the existing literature demonstrates the risk-taking nature of creative individuals as well as the "risky side of creativity." However, many questions remain concerning the role of risk-taking in creativity. One key reason is that creativity is a multifaceted construct straddling multiple phases (e.g., preparation-incubation-illumination-verification or generation-appreciation/evaluation), and in successful entrepreneurs risk-taking may play a key role alongside other personality traits such as openness, extraversion, and curiosity. Similarly, risk-taking is not a simple, homogeneous construct, despite always being regarded as a distinguishing factor of creative individuals. The role of risk-taking in creativity may be modulated by many factors, such as emotion and individual difference variables such as goal orientation. In the same way that risk-taking is defined as the trait of being afraid of the unknown and arousing curiosity, the unknowns of risk-taking in creativity should not make creative individuals afraid, but should instead stir their curiosity and drive to clarify it for themselves.

Uses of Photography

Photography has served many purposes, including journalism, advertising, portraiture, and social media. It has also been used extensively within psychological science. One of the most historic distinctions in psychology is that of stimulus (or antecedent event) and response (or resulting behavior). As stimuli, photographs have quietly contributed much to psychological science and therapies over the last six decades. Photographic stimuli have served a variety of research uses, in studies of emotion and facial recognition, physical attractiveness biases, as well as appearance and stereotyping. Studies of physiological and attentional responses on occasion have used emotionally intense photographic stimuli. Photographs have also been useful in the study of race, life narratives, gender roles, gender effects in smiling and social connection, and the sharing of cell phone images. More broadly, social scientists have used photography to appreciate varying educational environments, inner-city life, and homelessness.

In the clinical realm, photographs have been reported useful in psychoanalytic treatment, family therapy, self-esteem and identity-oriented counseling, behavior therapy, grief therapy, rehabilitation counseling, adolescent alcohol use, and various art therapies. A rapidly expanding area of study is that between social media or selfies and body image, body dissatisfaction and eating disorders. Indeed, the last 10 years has witnessed exponential growth in clinical reports that incorporate photography, although generally not with a focus on creativity. Whereas clinical uses hope to facilitate communication or self-reflection, research uses of photography seek to impact human behavior be it physiological arousal, affectional, anxiety, or prejudicial responding. Combined with originality, this capacity to impact is a key component in most definitions of creativity—namely that the creative product has utility or works for some purpose. Clearly, photographs as stimuli have many psychological uses. But only recently has the photographic response been studied, and as such it has become a tool in the study of creativity.

Creativity stems from the interaction between personal characteristics, process, and environment to produce novel and useful products understandable within a social context. Subsequent sections will describe the different components of photographic creativity: the process of creating photographs, the personality and aptitudes of the creative photographer, the photograph as creative product, and the environment/press or the social aspects of creative photography. First, we touch on what makes photography unique among creative arts.

Unique Aspects of Photography

Photographic documents are not the creations of an idealizing imagination that responds to the imperfections of reality with a dream of beauty. Instead, they are the trophies of a hunter who looks for the unusual in the world of what actually exists and discovers something exceptionally good. Rudolf Arnheim, 1986.

Photography is a relatively new domain. The first successful photographic process, a daguerreotype, was a creative technological breakthrough in 1839. The development of photography solved several problems of representation in drawing and painting (e.g., depiction of foreshortening or unusual angles) and influenced painters, for example Degas. It can be argued too that photography took over painting's imitative purpose and opened it to a higher level of abstraction.

Unlike other visual media, for example painting, photography is distinctly utilitarian due to its less arduous process. Nowadays, given the ubiquity of cell phone cameras, there are millions of amateur photographers whose primary goal is not to produce high quality creative works but to preserve and share personal memories. The ease of making photographs deflated the value of photography as an artistic medium in the eyes of the art world. Despite the continued skepticism about the value of photography as art, by the 21st century, it has been established as part of the art market. Photographs have become valued and widely collected as status symbols. New York's Museum of Modern Art (MoMA) started its photography collection of modern photography in 1930 and has

expanded it to over 25,000 photographs. Experts in the art world mark the early to mid-1970s as the beginning of recognition of photography as an art form with the start of regular and dedicated sales of photographs at major auction houses.

Technique and tools dictate creative behaviors: photographers are often in motion and painters are not. Photographers' work involves anticipation, constant scanning, vigilance, situation awareness, bursts of activity and production of many images, most of which are never shown to the public. Photographers subtract or distill images through the outside-in approach. Thus, creative problem solving in photography stresses subtraction and selection. Photographers capture and select already existing slices of reality through responding to *decisive moments* (Cartier-Bresson, 1999). Compare that to the intense additive, multi-layered creative process involved in writing a novel or composing an opera.

The capture and selection of images can also imply a *violence metaphor* where photographers "point-and-shoot" a scene (Sontag, 1977), trap a moment in time or a *theft metaphor* as in "take the picture" (Milgram, 1977). There is a fear of being photographed. It may be linked to the violence metaphor or the potential unfairness of the exchange between the photographer and the photographed. This potential for photographic exploitation can be seen especially in travel photography where researchers observed that the photographed populations may fear that photographers will use the images in a detrimental way. Some are also fearful of cameras due to religious prohibitions or superstitions.

Technical improvements in photography over the years have shortened processing times and produced increasingly higher quality images. With a quicker and more economic production of durable photographs, technical details became less important and content became more important. Photography paradoxically became both an art form and a way to mass produce snapshots. It is an extremely democratic art form.

Process of Creating Photographs

The camera is a sketch book, an instrument of intuition and spontaneity, the master of the instant which, in visual terms, questions and decides simultaneously. In order to give a "meaning" to the world, one has to feel involved in what one frames through the viewfinder. This attitude requires concentration, discipline of mind, sensitivity, and a sense of geometry. It is by economy of means that one arrives at simplicity of expression. Henri Cartier-Bresson, 1999.

I have a way to photograph. You work with space, you have a camera, you have a frame, and then a fraction of a second. It's very instinctive. ... in this fraction of a second comes your past, comes your future, comes your relation with people, comes your ideology, comes your hate, comes your love—all together in this fraction of a second, it materializes there. Sebastiao Salgado (From 2007 LA Times Interview).

Empirical research on photographic expertise is scarce. However, guidelines used by photography educators can provide insight on the creative process in photography. The process of creating a photograph involves research, experimentation, persistence but also accident and luck. Pasteur's famous quote "chance favors the prepared mind," while applicable to all domains requiring mastery, is particularly relevant to photography where often a split second separates master work from products that are common and uninteresting.

The creative challenge in photography is to show reality and yet modify it; make it look original but communicate with viewers. Just as in other creative domains, successful photographic process needs to be scaffolded with years of training in technique, equipment, design principles, subject matter, selectivity, and presentation. There is an abundance of instructional literature on how to take compelling photographs. Photography training involves learning to work with light, color and composition within the image frame, visual design and technical tools like figure/ground, lines, shapes, focus, exposure, rhythm, motion, depth, visual weight and optics. To bolster creativity, photographers might experiment with unusual lighting, angle, exposure, camera placement, filters, lenses, composition, and layout. As compared with amateur photographers, professional photographers are more likely to detect and describe photographic flaws (as defined by a separate sample of professional photographers; Serafin, 2013). These include lighting, lens, composition, and subject flaws. Photographic expertise allows for creating images high in both technical quality and aesthetic value. Talent is also an important contributor though difficult to define for specific domains and hard to separate from expertise.

Aside from discussion of technical matters, many photographers and photography educators touch on aspects of intuition and luck (or serendipity). The challenge of describing photographic process lies in retroactively tracing short (sometimes very short) creative events. One of several goals of photography instruction is the honing of photographic intuition and visual fluency. Photographic approaches are at least in some part related to the dynamics of the photographed subject/scene. Between reactive shooting and full control in the studio there are many in-between approaches to how photographers work. All rely on fast process and slow process to different degrees. Contrast sports photography where intuition dictates when to press the shutter in reaction to the *decisive moment* with still life photography which calls on powers of reflection and questioning. Several photographers have elaborated what they mean by intuition. Some remarked that great photographs can be created through an unconscious process, ahead of their conscious ability to understand it.

Photographic work, just like other types of creative work involves solving ill-structured problems which involve sudden insights or a-ha moments. Intuition and state of mental readiness go hand in hand in this process. Intuition and insight are separate

phenomena although they are both part of creative problem solving. Intuition involves changes in tacit knowledge whereas insight is sudden awareness of a solution. Photographers prime their minds with visual material in hopes of successfully portraying an idea. This process strengthens their photographic intuition and increases the chances of arriving at insight/solution. Practice through taking many photographs is very important in developing expertise in photography and bolstering intuition. From the perspective of cognitive psychology, practice in perceptual-motor domains like photography develops procedural schema. In such domains working on problems with one's body is more important than declarative knowledge.

Communicating intent in a photograph is another important aspect of the process. A photographer may for instance choose between a conventional and an experimental approach. For example, a wedding photographer may capture formal or journalistic style photographs or a mixture of both. Photographic intent is trained through deliberate looking, framing and taking many shots. Skilled judges of photography can quickly detect intent or a lack thereof. Photographers train their ability to decide whether to react or to plan an exposure, show greater or a lesser degree of complexity and ambiguity knowing that the less ambiguous the image, the more immediate the message. In a highly ambiguous image the photographer delivers a visual punchline so to speak by, for example, making the key subject less central in the overall composition and causing the viewer to experience a *delay* in detecting it.

The limited psychological research, educational literature and photographers' accounts distill three key elements of the photographic process: space (where to stand), time (when to release the shutter) and selection of the best photos. The first two elements involve constant fine tuning between camera angle and timing. Expert photographers are keenly aware and usually able to reason whether they might or might not be able to get the desired image and if they fail to capture it, they can explain why and how they would attempt to successfully achieve it. Empirical investigations mimicking the actual creative process of taking photos have used computer photo-cropping tasks using a still image and a video to test the space, time and selection aspects of the process (Serafin, 2013); results showed that professional photographers outperformed novices on all tasks when final products were judged by another group of expert photographers. Professional photographers are also more discriminating in judging photographic quality. The same study has shown that originality was not strongly related to overall quality and future research on *creativity* ratings should specifically target final products' novelty and appropriateness to context.

Photographers main challenge is what to include and what to omit from the image frame. The frame dictates photographers' decisions. Overall, the selection skill is key to the photographic process, from the initial subject and location selection, through the selection of when/where to capture an image to the selection of best images from contact sheets (paper or digital) and final selection for publications or exhibitions (the latter task is usually shared with editors and curators).

It has been suggested that there are two kinds of photographers based on how they engage in the process: those who take photographs and those who make photographs. The former are objective visual reporters, the latter are creators who stage and direct what to put in front of the camera. This dichotomy appears in photographers' accounts and is most likely related to the degree of immediate conscious effort, picture making being more deliberate. This distinction is familiar and useful to creativity researchers. Also relevant is the concept of creative finders (conceptualists) and seekers (experimentalists). These concepts deserve further study in creative photography.

Person Factors in Creative Photography

One approach to studying the person who engages in creative photography has grown out of Robert Ziller's (1990/2000) auto-photography technique. Initiating his work in the late 1970s, Ziller referred to the "phenomenological use of photographs" but subsequently he referred to the technique as auto-photography. Basically, participants were invited to take and select photos that answer the question "who are you as you see yourself?" Engaging in this process is responding to "an invitation to creativity" that potentially displays "rich revealingness" to personality that questionnaires cannot. Ziller conducted content analyses of participants' photos using disposable cameras; in two studies he found associations with "aesthetic" orientation. Aesthetic photos were those including "art, trees, lakes, ponds or flowers." They were more often included by shy than non-shy persons and less often by delinquents than by age-matched controls. Ziller's work included numerous studies extending far beyond the realm of creativity.

Dollinger and colleagues built on this notion of revealingness by rating the richness of college student 20-photo photo essays and exploring the correlates of what they identified as the quality of individuality or "creativity applied to the self." The distinction between least and most individualistic photo essays can be best seen in the descriptions of the low and high end of the rating scale for training new raters, described thusly: Level 1: *Concrete, unimaginative or dull style, commonplace and prosaic photos, repetitive content.* Level 5: *Abstract, metaphoric with many photos having deeper meanings; imaginative; creative interpretation of the photo essay task; aesthetic or artistic sensibility shown; self-expressive; self-reflective; interesting variety of themes and photos.* Low-rated photo essays typically depicted very stereotypic lifestyles (e.g., "self as partier" or "I am my pleasures and favorite things") or looked like family albums and in that sense appeared to be almost interchangeable with one another, and thus low in individuality or richness. Intermediate-level photo essays typically included aspects of the self in various roles, thus conveying more differentiation to the self but without integration and little creative expression. Highly-rated photo essays used aesthetic qualities, metaphor, and poetry and in the process revealed greater complexity, depth, and uniqueness to the self. Viewing the latter style of photo essay evokes the same responses desired by most professional photographers and photo editors: something authentic that touches the viewer, an emotional response, sense of "common humanity" with the subject, or the individuality of the photographer (Jaeger, 2007). Thus, the most individualistic photo essays emotionally touch the viewer and draw him or her into more detailed study of the photos and words used.

In the course of this research program, over 2500 college students participated by devising auto-photographic essays that included verbal commentary, as well as completing questionnaire data on potential correlates. Participants were typically about 70% non-Psychology majors in their third or fourth years of college with about 65% being female. Using Amabile's technique, 3–5 judges reviewed all photo essays independently, yielding reliabilities of 0.86–0.94. Then averaged ratings were correlated with a variety of personality, attitudinal and values measures. Numerous studies showed that, as with creativity generally, Openness to Experience was the most consistent and usually largest personality correlate of individuality/richness. However, Openness was not the only big-five correlate; Introversion and in some cases Agreeableness and Neuroticism played a part. The many personality, demographic, attitudinal and ability correlates suggested four themes that run across the nomological network (Dollinger, 2017).

Verbal Ability. First, individuality/richness consistently correlated with an inquiring intellect including vocabulary knowledge and college admission test scores but also such correlates as trait curiosity, breadth of cognitive interests, reading interests, need for cognition, investigative vocational interests and (a negative correlate) anti-intellectualism. Using Pennebaker's Linguistic Inquiry method, individuality also correlated well with *cognitive* word use in the photo essay itself. This pattern fits with and expands the meaning of the intellectual aspect of Openness to Experience in the five-factor model.

Personality. Reflecting the aesthetic aspect of Openness, a second theme was the desire to be creative, unique and self-directed. Those who devised individualistic photo essays produced more creative drawings and other products, and reported more creative accomplishments — both in contemporaneous studies while in college and in a small seven-year (post photo essay) follow-up. In values surveys and other ways, individualists had disdain for conforming to norms. Whereas their more conventional peers tended toward conservative values, individualists were more liberal and also imagined their futures as including more culturally-diverse experiences that may promote their own creativity and help them appreciate that of others.

Alienation. A third theme was negative emotionality. Compared to their conventional peers, individualists scored lower in self-esteem and they reported greater loneliness and alienation. Although they were about as likely to be involved in romantic relationships, individualists defined their relationships less in terms of fusion or overlap with the partner, and more as separate equals. The identity development of individualists is also relevant here; they tended not to follow the guidance of family or peers, nor did they emphasize social or collective identities. This is evident too within their photo essays: individualists showed fewer social connections (e.g., people touching) and made fewer references to friends. Individuality also correlated at times with negative or abusive life experiences, and with greater expectations of distressing or physically threatening events in their futures. Devaluing *recognition*, individualists were not particularly self-promoting, and in the follow-up study, they devalued the importance of relationships with work supervisors. However, they were not necessarily narcissistic (near-zero correlation) and didn't typically desire individuation in the sense of recognition and standing out from the crowd. All in all, this pattern of correlates showed that individualists could be alienated but strived to find their own life paths.

Wisdom. In accord with several developmental psychological conceptualizations, the correlates of individuality suggest interiority and maturity. Across different studies, individuality/richness ratings correlated with age, ego development, and with mature values. In terms of individual rather than composite values, individuality correlated with a contemporaneous valuing of *wisdom* and the tendency to devalue extrinsic rewards at work seven years after doing the photo essay. Within their photo essays, individualists' word use reflected insight and tentativeness plus metaphysical themes like death and dying (but not leisure interests), also suggesting "interiority" and wisdom. Rich photo essays were created by those who rejected superficial identity concepts as self-defining and those who focused on inner aspects like their dreams or imagination. Individualists were more likely to have experienced personal therapy, presented more vivid dreams, and were more psychologically minded. Their reading interests were more intellectual as opposed to focusing on romance, sexuality, and sports. In general, individualistic young adults had a more serious approach to their current lifestyle, reflected in their greater investment of time in study and their lower likelihood of depicting alcohol within photo essays. Taken together, this set of correlates suggests wisdom, maturity and inner-direction in participants who devised richer photo essays. In short, the four sets of correlates showed that richer individualistic photo essays were associated with verbal ability, an openness to inner, and aesthetic worlds, an inclination to march interpersonally to "a different drummer" and a wisdom and seriousness of purpose directed toward the meaning of their lives.

Photograph as Creative Product

Generally, photographs are defined as pictures formed by light falling on photosensitive surfaces and then stored on paper or digital media. Although photographs belong to the domain of visual media, creative photographs specifically exist within visual arts as evidenced by presence of photography in some of the influential current art publications (*Art News*, *Aesthetics*, *Apollo* and *Art Review*). Photographs serve aesthetic and practical purposes and have become ubiquitous as a mode of communication in modern life. Technological advancements in photography (e.g., shorter exposure times, inventions of color and digital photography and post-production) have been utilized in advertising, news and more recently social media.

It is hard to separate the aesthetic from practical purposes of photography especially when considering the aesthetic value of photographs made for purely practical reasons and with minimal human directed creative effort (e.g., Hubble telescope images of space, diagnostic imaging of brain matter, or microscopic images of cells, all of which blur the boundary between the practicality of science and the aestheticism of art). Similarly, the distinction between fine art and commercial photographs is sometimes not

evident. One way to distinguish between the two categories is in the timing of when the need or value of photographs is established. Commercial photographs result from assignments by external agencies (magazine editors, art directors) where the value is established ahead of time. Fine art photographs, on the other hand, are created first and their value is later evaluated. Commercial photographs are also often presented as series of best and lesser quality images to preserve flow and story whereas fine art photographs displayed in galleries are usually a smaller set of images, all superior quality.

The perceived value of photographs is a result of challenges presented to viewers. Successful solutions to visual problems result in pleasant viewing experiences. Viewers' experiences of art can be seen as a "mirror" model of art making and art perception. In this model, early stages of art viewing correspond to the final stages of art making and later stages of viewing correspond to earlier stages of art making, with added layers of emotional valence, ambiguity, social context. Successful visual art takes the viewer from the initial automatic interest in technical excellence, through intermediate memory-based processing of style, typicality, content to final meaning-making achieving a deeper understanding of the work's cognitive and emotive qualities (Tinio, 2013). Similarly, successful creative photographs engage viewers to go deeper beyond the technical excellence. Consider the number of choices photographers have when capturing a photo: conventional vs. unconventional angle, spontaneous vs. planned, documentary vs. expressive, simple vs. complex, clear vs. ambiguous, and still vs. dynamic (Freeman, 2007). This complexity in process seems to mirror the complexity (and creative value) of photographic images.

Psychological research on aesthetics supports ideas by photography educators and graphic design scholars. Photographs as creative products possess levels of *visual power* which refer to their *arousal potential* or their capacity to induce stimulation. Arousal potential can result from intensity, novelty or depth of meaning of photographs. More specifically in photography, visual power is related to format, pleasantness, expressiveness, viewers' familiarity with content, complexity and content type, sharpness, contrast and grain as aspects of technical quality, and challenges to visual processing introduced by photographers (i.e., via framing, cropping, peak-shift effect, and other techniques). The need for visual power varies with the characteristics of audiences such that highly homogeneous audiences need higher visual power.

Indeed different types of viewers judge the same images differently. Expert photographers, for instance, have a more varied set of aesthetic judgment criteria than non-experts and therefore are better at detecting complexities present in high creativity photographs (Serafin, 2013). Expressive and uncertain photographs appeal to expert photographers whereas familiar and pleasant photographs appeal to non-experts. More research is needed on levels of visual power and complexity of photographs, from physical, through visual grammar/design to deep cognitive, emotional and social meanings.

Photographs are most like the products in creativity research when they are evaluated in juried competitions. Elsewhere, Serafin and Dolinger (2017) compared the published views of five judges of professional photographic competitions. While varying widely in the number of elements considered, the comments translated to three basic judgment dimensions: (1) creativity; (2) photographic technical quality, and (3) genuineness or authenticity of content. While creativity is judged separately from technical aspects, it is rare for photographers to define what they mean by creativity, using an implicit assumption of "knowing it when I see it." Although most juried competitions do not intentionally use Amabile's Consensual Assessment Technique, they do share this common assumption.

Press/Environment in Photography

Any consideration of environmental press in photography necessarily recognizes the outer-world focus of this art. Arnheim described photography as a less controlled and thus a less creative process since it is dictated by the environment (an 'outside-in' approach) as opposed to control through medium and an artist's labor (an 'inside-out' approach).

At the onset, art critics were ambivalent toward photography. They recognized its value in preserving subjective experience yet they often expressed anxiety over what they perceived to be its destructive power. The concept of *disruptive technology* (a technology that disrupts and often replaces older technology reshaping the domain) was not introduced until much later and people of the time were not yet exposed to the fast-paced changes in technology and innovation that we experience today. Photography signified modernism and anxiety. Anxiety and changes in technology are true of photography to this day and undeniably contribute to the pressures experienced by photographers.

Artistic photography, like painting, has been used to produce works that evoke aesthetic experiences in a wide audience. Like painters too, photographers have congregated, created styles, and formed groups as part of *creative ecosystems*. One example is The Camera Club of New York founded by Alfred Stieglitz in 1884. Photojournalism became a domain and with it, the first photographic agencies were formed. These organizations reflect the sociocultural aspect of photography where expert and nonexpert audiences accept or validate photographs as creative. This sociocultural validation marks the final stage in creative production.

Photography today encompasses several sub-domains. As an example, educational offerings at the School of Photography at the Academy of Art University in San Francisco include commercial, documentary, fashion, fine art, still life photography and photo illustration. These map onto their respective career opportunities. Photography is an extremely competitive field where talent needs to be honed through supportive and challenging training environments. Budding photographers need tools to create cohesive bodies of professional work representative of their individual styles. The breadth of sub-domains in photography influences training. Street photography techniques are different from fine art photography tools and concepts. The

quality of photographs increases when one compares photojournalism or street photography to fine art photography. However, the general process is basically the same: “enthusiasm for subject, careful planning, working situation through many images” (Hurn and Jay, 2008, p.39). The difference in quality may come as a result of the selection process; journalistic photography is utilitarian and needs to fit with the immediate goals of the project whereas in fine art photography the final choices are up to the artist.

Today’s photographers experience pressures that did not exist 20 or even 10 years ago. These include *data smog* or the overwhelming quantity of visual digital data, an associated shortage of gatekeepers (editors, reviewers, curators) and the very heady possibility for one’s photos “to go viral.”

The cost of professional photographic equipment may be prohibitive to some and thus limit the sample of photographic talent to wealthier societies and individuals who can make the hefty initial investment despite the competitive and unsteady professional future. In addition, with heavy photo gear there often is a higher than average risk of injury in some subdomains which may partly explain why, at least in photojournalism, there are more male than female photographers. For those who secure careers in photography, the stress on utilitarian aspects may stifle their creative freedom and expression. In addition, they may need to supplement their income through unrelated work. Practicing photographers also mention the solitary nature of their work; they often wait for decisive moments and fast bursts of activity rather than work in a linear, logical fashion which may be more conducive to social activities. Especially nowadays, photographers express anxiety over being replaced with hordes of amateur photographers equipped with camera phones. To cope with the pressure, many photographers diversify their skill sets by adding video production skills.

What is next? Some predict that the optics in photography are as good as they can get and the future of photography is computational as in writing code. Others mention artificial intelligence, phasing out of some technologies, constant connectivity and virtual reality. Photographers will have to continue to adapt to more and more rapid photo technology revolutions. In addition, they need to continue to keep in mind ethical issues in photography, particularly relevant in photojournalism, and the value of balance between creativity and authenticity. Photographers might also consider that the monetary value of art photographs is influenced by artists’ reputation, quality and timing of printing, size of the series, and size of the edition.

Concluding Comments

Creative photography emerged to express a subjective need for visual communication. Creative behavior has evolved across various cultures suggesting its important survival value for society. There exists a range of creative photographic products; some are universally acknowledged as high in artistic value and some possess a more locally appreciated creative value. Compare Dorothea Lange’s portrait of a migrant mother with countless other family photographs of mothers or Ansel Adams’ Yosemite photographs with many others snapped by tourists. Perhaps, the former resulted from *eminent* creativity (genius) and the latter from everyday creativity. The best artistic photographers, who possess the requisite talent and expertise, are able to distill reality into a set of universal visual ideas and therefore more likely exhibit eminent creativity. Lange’s *Migrant Mother* communicates “this could be any mother, your mother or this could be you.” The best art photographs communicate timeless ideas whereas family albums and photographs on social media preserve personal memories.

There exists a tension between creativity and authenticity/objectivity in photography. Is creativity in photography desirable or even ethical? In some settings creativity is appropriate (photographs as aesthetic objects) whereas in others it may be less important than authenticity (photojournalistic images). In reality, even though aesthetic and creative function may not be used to override authenticity in photojournalism, time and time again photographers manipulate their work to achieve higher visual and emotional impact. Thus, it seems creative photographers will not be replaced by drones so long as we need a human mind to process which image will best communicate an idea. In closing, the impact of photography for human functioning was beautifully articulated by Sarah Laurent in a 2017 National Geographic piece:

In a deeply personal way I feel an image is a poem about time, about “staying the moment.” Photography can defeat time. Images can keep the memory of a loved one alive, hold a moment in history for future generations, be a witness to tragedy or joy. They can also change behavior, stimulate understanding and create a sense of urgency that will move people to action. Photography is the universal language that speaks to the heart.

Glossary

Convenience Sample A group of individuals who receive creativity tests or are otherwise involved in research even though they have not demonstrated any unambiguous creativity. They are, however, easy to find and thus a convenient sample with which to do research.

Crystallizing Experiences Some specific event occurring during childhood that creates and lifelong interest.

Elegance A simple and yet powerful idea or equation, such as $e = mc^2$

Evocative Experience Individuals often learn from experience, and they are sometimes recipients of what experiences are imposed on them, but other times individuals may have an impact on conditions which in turn create particular experiences. Creative individuals thus may both receive but also evoke particular experiences.

External Validity Generalizability of results, typically only provided by research conducted in a naturalistic setting and lacking in research conducted within a laboratory or controlled setting.

Gedanken Experiment A highly visual method where certain ideas can be tested. Apparently Albert Einstein frequently used this method for the exploration of possibilities.

Hyperspace An idea used in physics, as well as mathematics, that has recently been utilized in creative studies. The creative process may involve searching for ideas by looking in varied dimensions, and the number of dimensions may be infinite.

Internal Validity Experimental control, such as that provided by research conducted within a laboratory.

Intrinsic Motivation Drive that comes from within the individual and is often related to creative effort. It is in contrast to extrinsic motivation which is a response to incentives, rewards, bonuses, and the like—things outside of the individual.

Presymbolic Thinking Reasoning that occurs before symbols are assigned to thought so there is less or at least untraditional logic and great latitude.

Unambiguous Creativity The creativity that is manifested by famous people who have done something to change the way humanity views the world. They offer something original and effective, and what they offer is original compared to world wide standards and effective for large numbers of individuals. **Paradigm Shifts** Dramatic changes that follow from the gradual progress of normal science. Assumptions are questioned when there is a paradigm shift.

Introduction

The field of physics and those working within this field have received special attention in creative studies. There are a number of reasons for this. First, there are a number of interesting connections between the field of physics and creativity. Most obvious may be the creativity that leads to breakthroughs and progress in physics. Such progress may take the form of a *paradigm shift*, which occurs when assumptions which have endured for some period of time are suddenly rejected, the result being a radical change in how humanity, or at least scientists, view the world. A number of paradigm shifts have been described in various biographical reports and case studies of famous creators, which in turn have led to particular contributions to our understanding of creativity. These reports and case studies often point to the personalities of creative physicists and provide good examples of how the creative process is used. There are also messages about the impact of setting and context on creative work within physics. Another connection between physics and creativity represents this same *direction of effect*, with physics influencing our understanding of creativity. Consider, for example, the metaphors and models (e.g., hyperspace) which are used in physics but can frequently be applied to creativity studies as well. Then there is the worldview that is suggested by the field of physics—or more accurately, the various world-views—for physics tells us much about what is possible and what is beyond the direct experience of individuals. Not surprisingly, philosophies often follow from physics, and these philosophies in turn direct and constrain how human creativity can and should be used. Each of these connections is explored in this article.

Creative Physicists

Creative studies often look to and benefit from case studies of unambiguously creative people. One advantage of this kind of research is that the creativity displayed by the individuals studied is unambiguous. In other research creativity is difficult to define, or at least has a definition that has been debated for decades, and the debate is understandable when the creativity is ambiguous, as is the case when a convenience sample is involved in experimental research and when participants in this research (e.g., college sophomores, or these days, users taking tests on SurveyMonkey or the like) receive so-called tests of creativity under controlled conditions. In fact there are several reasons to doubt that tested creativity is authentic. The first is implied by the idea of a convenience sample: the participants may not be motivated to express their creativity; and if we assume that there is a continuum with highly creative individuals at one extreme and not as creative individuals at the other extreme, the participants could be less than outstandingly creative. Then there is the possibility that the experimental conditions impose constraints, which may inhibit creative expression. The research participants may behave in accordance with expectations, which makes original self-expression difficult. And highly controlled settings allow internal validity (a label for control) but are notoriously low in external validity, meaning that results would not apply outside of the experimental setting. This sort of thing is especially relevant to creativity because creativity is thought to involve spontaneity, intrinsic motivation, and autonomy, and such things may be precluded by experimental control. When unambiguously creative individuals are studied, on the other hand (see Howard Gardner's work on Gandhi, Freud, Stravinsky, Einstein, Martha Graham, for example, or Howard Gruber on Jean Piaget and Charles Darwin), the creators are not placed in any experimental situation. Instead they are living their lives, and those requirements of creativity just listed (e.g., intrinsic motivation) are not inhibited. In addition, they are famous because they have offered something to society that is highly original and effective. They have in fact changed the way the world is viewed. Their creativity is beyond question. It is unambiguous.

At the same time there are limitations to case studies. They usually look back at what has happened in the past, so generalizations to the future are questionable. Things may have changed—certainly they have changed! Thus the conditions experienced by those unambiguously creative adults, in the past, may not characterize anyone today. Along the same lives, the individuals under study may live idiosyncratic lives, so again, the findings may not generalize broadly. Then there is the fact that no experimental control is imposed, so cause-and-effect is not entirely certain. Consider here the theory of evocative development, where a child has an impact on family life and thus is not a mere recipient. He or she evokes experiences. This may again apply especially to highly creative children whose talents may be noticed by the parents and others and, as a result, changes are made to support the creativity. When this happens a child is not merely responding to experience but instead is also creating conditions which in turn lead to experience. Still, at the very least case studies offer hypotheses that can be tested later with controlled research. This can lead to respectable scientific theories of creativity which are both consistent with experimental research but also consistent with unambiguously creative cases.

The best-known case may be that of Albert Einstein. He changed the world and did so with some unique methods. These tell us something about how certain people use certain processes. Einstein used *Gedanken* experiments, for example, which are highly visual explorations of possibilities in physics. He supposedly imagined what would occur if two people passed each other while riding in trains moving in opposite directions, or what it would be like to ride on something moving at the speed of light. This gave him insights about relativity (e.g., riding on a beam of light would make everything else appear to slow and perhaps even stop). Interestingly, his ideas were elegantly mathematical (e.g., $E = mc^2$) and entirely theoretical, but decades later supported by experimental observations. Light has been observed to change as it passes close by a body that has powerful gravitational pull, just to name one example.

Howard Gardner's study of Einstein's childhood uncovered the importance of *crystallizing experiences*. In Einstein's case this occurred when he was a young boy and he was given a gift of a compass. Apparently he was fascinated by the fact that the compass could find the magnetic north pole, no strings attached, as if by magic. Note here an early fascination with magnetic waves, which can easily be associated with many of his adult *Gedanken* experiments about electromagnetism. Studies of Einstein's brain have also been reported, though here great caution is warranted. Assaying suggested that his brain may have had an abnormal amount of glial cells in the visual cortex, but his brain was not examined carefully until years after his death and the chain of evidence (i.e., the maintenance of the sample of his cortex) may not have been carefully controlled and monitored.

Tweeney (1996) examined a variety of physicists but focused primarily on Michael Faraday. The reason for this focus: Faraday kept a daily diary so Tweeney was able to explore thinking as it developed and changed. One very important idea to arise from Tweeney's research was that much occurs *presymbolically*. This can be contrasted with what he called the "traditional view." In his words, "In the traditional view, to understand thinking is to understand the process by which symbols are rearranged, modified, used, and so on" (p. 168). Tweeney much preferred an approach that he said was more consistent with what "William James (1890) referred to as a 'reinstatement of the vague to its proper place in the mental life'" (p. 254). Presymbolic processes occur before symbols are formed and do not follow the logic which is easily described. This is what makes them vague. Presymbolic processes may appear to follow no logic at all, though it is possible that there is a logic but it cannot be understood if the observer takes an objective perspective and relies on traditional logic.

This view is consistent with Miller's (1996) research on scientific creativity. Miller mostly wrote broadly about scientific creativity rather than physics, but some of his ideas are based on his examination specifically of electromagnetism and "atomic theory" (p. 113). One particularly interesting volume is Miller's (2008) *Einstein, Picasso: Space, Time, and the Beauty That Causes Havoc*. As that title suggests it examines Picasso and Einstein, an artist and a physicist—who never met. Yet they worked within the same era and are often attributed with introducing modernity. Was there some commonality, *Zeitgeist* perhaps, that influenced them both? Both

were influenced by Poincaré and his theory that there is a dimension beyond the ones typically perceived and acknowledged. For Miller, Picasso captured this new dimension in art, while Einstein wrote about it. Miller even claims that Picasso and Einstein were working on the same problem: “how to represent space and time at just the moment in history when it became apparent that these entities are not what we intuitively perceive them to be.” One important suggestion from Miller is that physics can be influenced by historical context—and by aesthetics. Recall here the idea of elegance, mentioned briefly above.

Miller (2009) took a somewhat similar approach in his volume *137: Jung, Pauli, and the Pursuit of a Scientific Obsession*. Pauli, recipient of the Nobel Prize in 1945, wrote about relativity but was probably best known for his *exclusion principle*. He also may have been first to recognize the existence of a particle that has no mass nor charge, namely the neutrino. He had a huge impact on the nascent field of quantum physics as well. He was, sadly, often unhappy, which took him to Carl Jung, student of Sigmund Freud and famous psychoanalyst. Jung is very well known, in part for his thinking about *archetypes*. So here again Miller examined a physicist but within a social context. And Jung and Pauli certainly had breadth in their thinking! Both felt that certain numbers have important qualities and represent critical processes in the universe. Hence the “137” in the title of Miller’s volume. 137 does represent an atomic constant, but a number of people, including Pauli and Jung, felt it plays a much larger role. One conclusion from Miller’s examination is that creative people, including certain physicists, benefit from open mindedness. They may even seriously consider ideas and concepts that strike the rest of us as questionable. Yet this open mindedness may in fact play a role in creative work.

Like Miller (2008), Leonard Shlain (1991) explored how physics is related to art. Shlain did note the differences between art and physics, but after analyzing various theories, including Einstein’s, and various artists, including Cézanne and Monet, Shlain offered the controversial theory that artists are aware of things before physicists. In fact, for Shlain, artists use ideas in their art which are later “discovered” by physicists. Sometimes artists beat physicists by 20 years, as was the case with the art of Cézanne and Monet who both painted as if they knew about the paradigm shift that would only much later be initiated by Einstein. Shlain offered other examples of this foreshadowing, including Jasper Johns and Andy Warhol. Apparently, physicists like Pauli are open minded, but not quite as open-minded as artists.

Physics Changing Theories of Creativity

Physicists often use metaphors in their work. Researchers studying creativity sometimes do the same thing—and sometimes the root of those metaphors can be found in physics. There are theories that describe the creative process using chaos and fractals, for example, as well as a fairly recent theory that describes creative thinking as an exploration of *cognitive hyperspace*. Some background must be given before this idea is defined.

That background involves the theory of divergent thinking, which is covered in another entry of this same volume, and often used in the creativity research. Indeed, tests of divergent thinking are probably the most commonly used assessment in this field. The idea of divergent thinking goes back to J. P. Guilford. He built a large Structure of Intellect model in the 1950s and 1960s. It included 180 different “cells” and types of thinking. This large theory was discredited, but mostly because Guilford used a subjective method in his (factor analytic) statistics. Still, the distinction between divergent and convergent thinking has proven to be enormously useful in creative studies and related fields. For Guilford, thinking which takes different pieces of information and moves toward one correct or conventional cognitive results (e.g., a solution or idea) requires convergent thinking. Thinking which instead leads to a number of varied solutions and ideas requires divergent thinking. This really is itself a pair of metaphors. Just as roads or waterways may converge or divergent, so too may thinking, though in actuality there is probably no physical meeting or separation, as there is in the case of roads or rivers.

As a matter of fact Acar and Runco (2017) pointed to exactly this fact, that there is no actual divergence in tests of creative potential which purportedly assess divergent thinking. Acar and Runco described how a person can have a high score on a test of divergent thinking even though their cognition may not actually diverge. They cited associative theories where ideas are concatenated, one after another, and where an original idea is remote (quite removed from the original problem) and not divergent but actually just far removed in a straight, linear fashion. There is quite a bit of evidence for this: remote associates are often found when a person is given adequate time so their thinking may move from one idea to the next.

Acar and Runco thus proposed an alternative theory and method for testing, or at least for scoring tests. They referred to cognitive hyperspace, the idea being that creative people may have an idea (or solution), and then another idea. They may follow one path or direction of thought in a linear fashion. But their open-mindedness and creative potential allows them to redirect their thinking. The cognitive pathway might make a dramatic turn. This can be seen as a turn to a perpendicular path. Ideas along this path will appear to be quite different from the original ideas. Then the person may make another turn in their thinking and explore another perpendicular path. If this person was following actual pathways, perhaps talking a walk, they would be limited. They could only turn in a perpendicular manner very few times. If they could fly, that would add a perpendicular, but still he or she would be limited. But thinking is not limited in this fashion. Thinking can take one dramatic turn after another. Creative cognition can go into hyperspace, which is a concept used occasionally by physicist and mathematicians. For Acar and Runco, this may very well be a good method for finding highly creative ideas. They offered some very tentative support for the benefits of exploring cognitive hyperspace. What is more relevant, for the present purposes, is that this exemplifies how creativity research may draw from physics. As mentioned briefly above, other concepts used in physics (e.g., chaos and fractals) have also been used, albeit in limited ways, in the creativity research.

Conclusions

Paradigm shifts in physics require creativity on the part of the physicist. In fact, it may be that more incremental steps also require creativity. No wonder there are quite a few case studies of physicists, even in journals devoted to creativity, such as the *Creativity Research Journal* (Miller, 2008; Tweney, 1996). In addition to the examples described in this entry, Raina (2003) wrote about Erwin Schrodinger and Gooding (1996) about Michael Faraday. Recall that the information obtained from case studies may best be used to formulate hypotheses for later experimental study. It may not generalize. Still, case studies are fascinating and often consistent with other theories of creativity.

If this entry was longer it would certainly be worthwhile to discuss Erwin Schrodinger. That is because he used a method much like Einstein's Gedanken experiments, and in fact his most famous idea was an extension of something first considered by Einstein. Schrodinger really extended the original idea and the experiments known as *Schrodinger's Cat*. Physicists see this as a critique of the *Copenhagen Interpretation of Quantum Mechanics*, but for most of us it merely demonstrates the role of paradox in quantum physics. Simplifying, a cat is in a sealed box, and is poisoned, but since direct observation is impossible, a quantum view is that at some point the cat is both dead and alive.

This is especially relevant to recent creative studies because, more and more, the role of paradox in creative thinking is being recognized. Albert Rothenberg is well known for his work (also summarized in the *Creativity Research Journal*) on Janusian Thinking, and it involves paradox. Janus was the Roman god of doorways and could see both in and out at the same time. Rothenberg offers a number of examples of how creative breakthroughs—including the idea of *complementarity*, where particles simultaneously display characteristics of waves and quanta—are well explained by describing how the creator used Janusian thinking and what from an ordinary perspective appears to be paradox. Many others have used paradox in recent theories of creativity (Runco, 2016, 2019), including Ronald Beghetto (2018), who applied the idea to efforts to support creativity in educational settings.

The present chapter offers several case studies, which should be followed up with good experimental research. It also points to metaphor, visual imagery, openness to wide alternatives, cognitive hyperspace, presymbolic processes, and paradox as possible methods used for creative work in the field of physics. More research is needed to determine which of these, if any, is in fact idiosyncratic and only useful in physics or perhaps useful more generally in other sciences as well.

Pretend Play

Play is a universal phenomenon of childhood. Play comes in many forms, but the form of play most relevant to the area of play and creativity is pretend play. Pretend play involves the use of fantasy and make-believe and the use of symbolism. Pretend play also involves affect and expression of emotions. [Greta Fein \(1987\)](#) conceptualized pretend play as symbolic behavior where one thing is treated as if it were something else; a Lego becomes a milk bottle or a block becomes a telephone. Fein also stressed that pretend play is charged with feelings, so that affect is intertwined with pretend play. She viewed pretend play as a natural form of creativity.

Much of what has been written about the development of creativity in children has focused on the development of play. [Keith Sawyer \(1997\)](#) conceptualized pretend play in young children as improvisational in that it is unscripted but also has loose outlines to be followed. Much of creative performance involves improvisation.

[Lev Vygotsky](#) theorized that imagination developed out of children's play. He stated: "The child's play activity is not simply a recollection of past experience but a creative reworking that combines impressions and constructs from them new realities addressing the needs of the child" (1930/1967, p.7). Through play, children develop combinatory imagination-the ability to combine elements of experience into new situations and behaviors. Combinatory imagination is important in both artistic and scientific creativity.

Play follows a developmental process. Before 2 years of age, children play with objects similarly no matter what their actual functions are. Around 2 years of age, children discover that objects have specific functions. They recognize that a telephone is used to talk to someone and a plate is used to hold food. Also around the age of two, children begin to discover pretend play. They are able to pretend that a circular block is a wheel. Children continue to develop pretend play abilities throughout their childhood-until about 10 years of age. There are individual differences in how frequently children engage in pretend play and over what period of time during their childhood. In pretend play, children are able to think symbolically and not be confined to a single use of an object. The child is able to transform the object to represent many things but is also aware of the primary use of the object.

As children develop, their play becomes more complex. Jeffery Dansky, in his [1999](#) review, pointed out that in high level play, children display all seven dimensions of original thinking described by Roberta Milgram: associative fluency, imagery, curiosity, fantasy, problem finding; metaphoric production; and selective attention deployment. He concluded that individual differences in play have implications for individual differences in creativity. Dansky also theorized that adopting the "as if" frame in play may open the door to a mode of problem solving where one can play with ideas and possibilities, which is so important in creativity.

Fein studied the pretend play of 15 preschool children who were master players. From her observations, she concluded that good pretend play consisted of five characteristics:

1. Referential freedom. The "as if" quality in play where one object is treated as if it were another, one person functions as if they were another, and time and place is as if they were different.
2. Denotative license. Pretend events occur and there is a divergent stance with respect to actual experience.

[☆] *Change History:* November 2019. Sandra Russ updated the text throughout the article.

This article is an update of S.W. Russ, K.M. Christian, Play, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 238–243.

3. Affective relations. Symbolic units represent affective relationships such as fear of, love of, or anger at. Information about affective events are stored and manipulated in ways that make affective sense for the player.
4. Sequential uncertainty. There is a nonlinear quality to the sequence of events.
5. Self-mirroring. The self is observed through a distance. Children are aware of the pretend quality.

Play and Creativity

In 1983, Nathan Kogan stated that the research on the play and creativity link was the most promising set of findings in the children's creativity literature in the previous decade. The promise of that early research has continued to be realized.

It makes theoretical sense that pretend play would relate to creativity because many of the processes involved in the creative act occur in pretend play. In order to study play and creativity, one must be specific about the underlying processes involved.

Sandra Russ in 2004 reviewed the literature and developed a model of cognitive and affective processes that occur in both play and creativity. Through pretend play, children practice cognitive processes such as divergent thinking, organizing thoughts into a narrative, flexible thinking, and the use of symbolism and fantasy. Pretend play also is a medium for affective processes to be expressed. Children use play to express emotions and affect-laden fantasy, to regulate emotion, and to experience the joy of the play experience itself. Interpersonal processes can also be observed in pretend play. Characters communicate and interact with one another and role play different characters who have different perspectives about events.

Pretend Play and Creative Cognitive Processes

Dorothy and Jerome Singer in many of their writings suggested that areas of cognitive development are facilitated by pretend play abilities. Play helps the child to expand vocabulary and link objects with actions. For example, a child can learn words and actions by labeling objects and their functions through play—"I drink from a cup" or "I go in a car." Play also helps the child develop object constancy and form event schemas and scripts. For example, a peek-a-boo is very exciting for a young child who learns that even though mother is hiding, she will return. Pretending to play house or doctor is another way children learn about their world. Pretend play also helps children learn strategies for problem solving, develop divergent thinking ability, and develop a flexibility in shifting between different types of thought (narrative and logical). Singer and Singer thought that the last two categories were especially important in creative thinking.

Cognitive processes that are thought to be important in creative thinking are divergent thinking, transformation abilities, and insight. Divergent thinking is the ability to generate a variety of ideas. J. P. Guilford identified divergent thinking as important in and unique to creative problem solving. A typical item on a divergent thinking test would be "How many uses for a newspaper can you think of?" Divergent thinking involves free association, broad scanning ability, and fluidity of thinking.

Guilford also proposed that transformation abilities were involved in creative thinking. Transformation abilities involve a flexibility of thought that enables breaking out of an old problem solving set and seeing a new way to solve a problem.

Insight into the solution of a problem is important in creativity. Early research on play and creative problem solving investigated play and insight ability. Studies found that play in children 3–5 years of age facilitated insight into a problem solving task. Brian Vandenberg concluded that all the studies had the consistent finding that play facilitated insightful tool use and enhanced motivational activity. Variables of task type and difficulty and age were mediating factors. He discussed the similarity between play and creativity in that both involve creating novelty and disregarding the familiar.

Much of the creativity and play research has focused on divergent thinking. Jerome Singer and Dorothy Singer (1990) thought of play as practice with divergent thinking, so there should be a strong relationship between play and measures of divergent thinking ability. Many researchers found significant relationships between play and divergent thinking, usually independent of intelligence. For example, Russ and her colleagues found consistent relationships between fantasy in play and divergent thinking in preschool children as well as elementary school children. She reviewed this research in 2014. In one longitudinal study, play in first and second grade children was associated with divergent thinking ability when they were in the fifth and sixth grades. Children who could use fantasy and imagination on a pretend play puppet task could generate more uses for objects (fluency) on a divergent thinking task four years later. The relationship between pretend play and divergent thinking remained stable over time.

Much of the research in this area has been correlational in nature, but there are some well-carried out experimental studies that have found that play facilitates divergent thinking. Dansky found, in several studies, that play enhanced divergent thinking in pre-school children. In one of his studies, he found that free play facilitated divergent thinking, but only for children who engaged in make-believe. It was the pretend element that was important. Some critics of this research have raised the issue of unconscious experimenter bias because the same experimenter gave the play and divergent thinking tasks. Peter Smith and Sue Whitney, in a carefully executed study, failed to confirm the hypothesis that play would enhance divergent thinking in pre-school children. However, it is also possible that introducing a new examiner between the play and the divergent thinking task broke the set that was being induced by the play. Thus, there would be no experimental effect of play on problem solving. Another important point is that there have been a number of correlational studies that did use different examiners for the play and divergent thinking tasks and did find significant relationships between the variables.

Although there is much evidence suggesting that similar processes are involved in play and divergent thinking, it is worthwhile to speculate on the actual cognitive processes that account for the link. Dansky's theoretical explanation was that the process of free combination of objects and ideas involved in play is similar to the elements involved in creative thinking. He thought that the free symbolic transformations inherent in pretend play created a temporary cognitive set toward a loosening of old associations. Others stressed the role of play in the development of flexibility in problem solving. Play provides the opportunity to explore new combinations of ideas and to develop new associations for old objects. The capacity to see old objects and ideas in new ways should aid in developing transformation abilities; that is, the ability to break out of an old set and see a new solution to a problem. Also, children's play behavior involves a search for alternate modes of relating to the object, a process similar to searching for alternate uses for objects in divergent thinking tasks. Anthony Pelligrini conceptualized that in play children recombine behaviors and develop flexible strategies. His research with rough and tumble play supports that concept.

In summary, much of the explanations about why play relates to creativity, and especially divergent thinking, have focused on cognitive variables such as cognitive flexibility, loosening of old cognitive sets, practice with associations, recombination of old objects and ideas and symbolic transformations.

Pretend Play and Creative Affective Processes

Pretend play is infused with affect for many children. Children use play to process emotions. J. Singer has discussed how play helps children organize their emotional experience. Affective processes also play a role in creative thinking.

Fein, Russ, and J. and D. Singer are all theorists who have stressed the importance of affect in play in the link to creativity. Fein proposed an affect symbol system that gets activated in pretend play and is important in creativity. An affective symbol stores information about emotional events and is manipulated and worked with in pretend play. Russ, from a psychodynamic framework, stressed the importance of pretend play in helping children to access emotional memories, fantasies and associations. Children who are comfortable letting their thoughts roam a broad spectrum of associations and memories that are affect-laden should be more creative. Singer and Singer thought that a cognitive-affective framework was central to exploring imaginative play.

Just as it is important in creativity to play with ideas and images, it is also important to play with affective content. Affect expression in play occurs from a very young age. Interestingly, when affect expression in the play narrative in children from 6–10 years of age was compared, there was no developmental differences found in the amount of affect expression over these years. In terms of stability of affect expression, Russ, Robins, and Christiano found significant relations between affect expression in children in play when they were first and second graders, and affect expression in play narratives when they were sixth and seventh graders. This finding suggests some stability in the tendency to express emotion and emotional themes in narratives across time.

Fein viewed affect as being intertwined with pretend play. She viewed pretend play as symbolic behavior organized around emotional and motivational issues. The proposed affective symbol system represented affective relationships which the child manipulated and elaborated in play. This system could be activated by pretend play or drawing and is important for creative thinking.

Russ, after reviewing the literature, proposed categories of affect that are important to creativity and also occur in play. These include:

1. Access to affect-laden thoughts and ideas. This is the ability to think about emotional content. Affective symbols would be in this category as would primary process thinking, a key psychoanalytic concept.
2. Openness to affect states and feelings. Experiencing the emotion is also important to creativity and children use play to express positive and negative emotions.
3. Affective pleasure in challenge and problem solving. This is the ability to experience pleasure and joy in play and to "get lost" in the play experience.
4. Cognitive integration, emotion regulation and modulation of affect. This blend of affect and cognition that is important in creative thinking and occurs in play. Emotion is in the context of a narrative.

Russ in 1987 developed the Affect in Play Scale (APS) to meet the need for a standardized measure of affect in pretend play. Until then, measures focused only on cognitive aspects of play. The APS uses puppets and blocks with standardized instructions in individual 5 min play sessions. The play is videotaped and coded for amount of affect expression in the play. Frequency and variety of affect themes is scored with a frequency count. Enjoyment and comfort in playing is rated on a five point Likert scale, as is imagination and quality of the fantasy narrative. There is also a pre-school version of the scale that uses a variety of toys with more structured instructions. Also developed was a brief rating version that rates the child's play in vivo and does not require videotaping.

Research using the APS with a variety of child populations and researchers has found significant relationships between affect in play and creativity. In general, children who express more affect themes in the play narrative are more creative. Affect expression in play has related to fluency and originality in divergent thinking, to teachers' ratings of fantasy ability, to creativity in stories, and to emotion in memory narratives. In most samples, these relationships were independent of verbal intelligence.

It is important to note that both positive and negative affect in pretend play relates to creativity. Happy themes like having fun and aggressive themes of wrestling or bickering are examples of positive and negative themes in play. Because play is pretend, there may be positive affect accompanying even the negative affect themes. Or the negative affect themes may be modulated in intensity by the child so that they are not too negative.

There is some evidence that the expression of affect in fantasy is cross-situational. Affect in play has related to expression of affect in memory descriptions and expression of affect themes on the Rorschach. The relation to affect themes in memory descriptions could have implications for creative writing. Children who develop the ability to think about emotion-laden memories and express affect in narratives would have an advantage in areas of creative writing where emotions and understanding the emotions of others is important.

Playfulness and Creativity

Playfulness is another general characteristic of play that is important in creativity.

It is generally accepted that a playful individual has an internal predisposition to interact within their environment in a playful way regardless of their exposure to tasks, contexts, or materials that may yield behaviors that are related to play. Lynn Barnett defined playful individuals as those who naturally possess the ability to frame or reframe their experiences in a way to provide oneself with "amusement, humor, and/or entertainment."

A pioneer in the research of playfulness, Nina Lieberman attempted to distinguish differences between play behaviors and playfulness as a trait in children. From her research she was able to delineate five components to describe this playfulness quality: physical spontaneity, cognitive spontaneity, social spontaneity, manifest joy, and sense of humor. Physical spontaneity referred to the level of movement and coordination during play. Cognitive spontaneity described the imaginative qualities of play and a child's willingness to assume different character roles and unconventional uses of objects. Social spontaneity emphasized flexibility in interactions with other children and a child's willingness to initiate play and interact with others. Manifest joy described a child's ability to express enjoyment and enthusiasm while playing. Sense of humor referred to a child's ability to clown around, tease, and joke with other children. Lieberman found that playful kindergarten children did better on divergent thinking tasks than non-playful children.

Building on Lieberman's work, Barnett (1991) developed a more reliable measure of playfulness which also supported that playfulness is a single characteristic that describes an individual's predisposition to play. Barnett and others explored relationships between playfulness and other personality traits. Barnett found that playfulness related to several personality descriptions, such as bright, active, aggressiveness, cheerful, self-confident, imaginative, impulsive, mischievous, and responsible. Other researchers found a strong relationship between playfulness and several adaptive personality traits like creativity, humorousness, emotional expressiveness, curiosity, openness, novelty-seeking, and communicativeness. In addition, children who were considered playful also demonstrated greater levels of positive affect, physical activity, communication, and imaginative and social behaviors in play than less playful children. Other researchers found a relationship between play and personality factors of positive mood, persistence, approachability, and adaptability.

Converging evidence suggests that children who are playful tend to be more flexible in their understanding of the world, more approachable, tend to initiate contact with others, and have an assertive style that may contribute to their ability to act adaptively when distressed. It may be that children who are naturally playful are more effective and efficient at dealing with their problems in their environment. Nonetheless, more research is needed to better understand the relationships between playfulness and positive adaptive behaviors.

Lieberman also discussed the importance of joy in playfulness. Children experience joy in play. Passion and the tendency to become absorbed in the task has been identified as crucial by many creativity researchers. To let passion and joy of learning develop in children is becoming increasingly difficult in our culture. Yet love of the task is necessary to help the individual tolerate all of the negative and frustrating components of the creative process necessary to make a major contribution. In play, children are beginning to experience the joy of getting lost in the task and doing something for the love of it.

Interpersonal Functioning

Vygotsky and Piaget were developmental theorists who believed that interaction through peers fosters problem solving and play development. Vygotsky identified a zone of proximal development, which includes tasks that are too difficult for the child individually, but are possible with guidance by adults or more skilled peers when the child is playing. Piaget also emphasized the importance of peers in the development of problem solving skills, but suggested the peers need not be more advanced. Through interactions with others at a similar developmental stage, children learn different perspectives, discuss possible resolutions, and decide on the best solution. Children develop problem solving skills, as well as advance their play skills, through this resolution process.

Pretend play is also related to understanding emotions of others, perspective-taking and empathy with other children. Paul Harris proposed that imaginative understanding may enable children to understand others' mental states and affective experiences. The research supports this proposition. Understanding the emotions and perspectives of others is important in a variety of domains such as fiction writing, poetry, screen-writing, play-writing, and song writing.

There is also a growing literature on the importance of having imaginary friends in childhood. Marjorie Taylor has done much of the research on the creation of imaginary companions during the preschool years.

Russ in 2014 summarized the play and creativity research and concluded that play is related to many of the cognitive and affective processes important in creativity. Much of the research is correlational but there are some well-designed experimental studies as well. Russ speculated that pretend play helps the child become more creative by:

1. Practice with free flow of associations that is involved in divergent thinking
2. Practice with symbol substitution, recombining of images, and manipulation of object representations
3. Expression of positive affect, which is so important in creative work. Playfulness and the love of the experience of getting lost in a task and experiencing joy
4. Expression of positive and negative affect themes in fantasy. The child develops access to a variety of memories and associations and manipulates affective symbols
5. Developing narratives that integrates and regulates the emotions
6. Expanding understanding of the emotions and perspectives of the other

There is definitely a need for more research that investigates the underlying processes and mechanisms that account for the well-established relationship between play and creativity in children.

Neurological Research

Recent research in neuroscience is relevant to pretend play and creativity. research. Neuroimaging studies have identified the default-mode network (DMN) as the brain system involved in spontaneous, self-generated thought (Beatty et al., 2016). This is the type of thought important in open-ended tasks requiring generating a variety of ideas. Pretend play is an open-ended task requiring self-generated thought. It is also the neurological network involved in incubation-the process of mind wandering and letting one's thoughts roam.

Beatty and his colleagues also identified the executive control network as being important in the creative process. The executive control network brings cognitive control and critical thinking functions to creative tasks. Creative tasks such as divergent thinking tasks involve both types of networks, an open-ended phase of idea generation and an evaluation phase that identifies solutions and refines the product.

Recent fMRI studies have found that there is a dynamic coupling between the default-mode network and the executive control network when people engage in different creative activities, such as poetry and musical improvisation. Vartanian reviewed research by Beatty and colleagues that found that more creative people had increased coupling between these two networks than less creative people. Vartanian suggested that there may be stable functional differences involving the coupling of these two networks in individuals. In other words, neurological differences may reflect better ability in creative individuals to switch back and forth between spontaneous thought and evaluative thought processes than less creative individuals. In pretend play, children switch between self-generated ideas and images and critical thinking skills required for creating a narrative. Pretend play provides practice with this switching activity.

Facilitating Pretend Play and Creativity

One way to foster creativity in children is through facilitation of pretend play ability.

There have been efforts to improve children's play skills. Many of these play training studies have been in an academic context rather than a therapeutic context. Smilansky's study in 1968 was one of the first to demonstrate that teachers could teach play skills. She worked with kindergarten children from low Social Economic Status (SES) backgrounds in Israel for 90 min a day, 5 days a week, for 9 weeks. The children who engaged in socio-dramatic play, with help from their teachers, showed significant cognitive improvement when compared with other groups. The teachers helped the children develop their play by commenting, making suggestions, and giving demonstrations. Play training has been found to be effective with mentally retarded populations. Additionally, in Austria, when compared with a control group, low SES elementary school children who were instructed in play 4 h per week had better divergent thinking skills and were happier in school.

One of the methodological problems with many studies in the play facilitation area is the lack of adequate control groups. Smith has consistently raised this issue in reviewing the play intervention literature. Smith stressed that adequate research design requires the inclusion of a control group that involves experimenter-child interaction of a form other than pretend play. He concluded that when this kind of control group is included, usually both the play group and the control group improve. Dansky reached a different conclusion after reviewing the play training literature. He concluded that many studies did have adequate control groups that controlled for involvement of the experimenter. Dansky concluded that there were consistently positive results in studies with adequate control groups that demonstrated that play tutoring, over a period of time, resulted in increased imaginativeness in play and increased creativity.

Lillard and colleagues in 2013 criticized the methodology of play and creativity research and concluded that there was no evidence that play facilitated creativity. Russ and Wallace (2013) reached a different conclusion, as had Dansky. However, Lillard's recommendations for rigorous play intervention studies using control groups and blind scoring, should be followed in future research.

Russ and colleagues investigated the effects of play intervention techniques on children's play skills and associations with creativity, coping, and life satisfaction. Participants were 50 first and second grade children in an inner city school (99% African-American). Children were randomly assigned to either the imagination play group, the affect play group, or the puzzles/coloring control group. Each participant met five times with a play trainer in individual sessions. A standardized play intervention was

used for each play group. This study found that the affect play group showed greater cognitive and affective play skills. The imagination play group showed greater affective play skills. It was also hypothesized that the play conditions would result in greater creativity, coping, and life satisfaction than the control condition. This turned out to be accurate with a significant effect of group play on creativity, coping, and life satisfaction.

The major result of this study was that the play interventions were effective in improving play skills. After baseline play was controlled for, the affect play group had significantly higher play scores on all play processes. These children had more affect in their play (both positive affect and negative affect), a greater variety of affect content, and better imagination and organization of the story than did the control group. The imagination play group also had significantly more positive affect and variety of affect than the control group. When we did a follow-up study of these children 4–8 months later, only the imagination group had improved play skills over time. Results for the affect group did not hold over this period. Also, the increase in divergent thinking did not hold.

The longer lasting effect of the imagination intervention on play skills is interesting and warrants more research. In general, the results are promising that a brief standardized play intervention can improve children's play skills, which may, in turn, enhance creativity, coping, and feelings of life-satisfaction. In a recent study, in a small group play intervention, after six small group play sessions that were facilitated by adults, [Hoffmann and Russ \(2016\)](#) found that children had increased imagination and affect in play, when compared to a control group who colored and did crafts. In addition, there was a transfer effect in that below-average players at baseline increased performance on a creativity task.

In a randomized controlled study with autistic children, [Kasari and colleagues, \(2006\)](#) found that a play intervention resulted in increased symbolic play. This was a very rigorous study that began the intervention at the child's current developmental level of play. The training involved modeling and prompting. Children in the play group, compared with the joint attention and control groups, had increased symbolic play that generalized to play with the mothers. This study is relevant to the area of creativity because children with autism have deficient pretend play skills. Techniques that facilitate play in these children should be effective with other groups as well.

[Erin Barton and Mark Wolery, \(2008\)](#) in a review of the literature on play with children with disabilities, concluded that there is a consistent relation between pretense behaviors in the child and adult prompting and modeling. However, there were many methodological problems with the studies. They did think that teachers could prompt pretend play in the classroom, but for generalization to occur, multiple exemplars of materials and multiple trainers should be used.

There is some research that guides parents in helping children to develop their play skills. Singer and Singer, in 1999, developed a video-based program for parents and other caregivers of preschool children that uses make-believe play to enhance literacy. This is a comprehensive program called *My Magic Story Car*. Children watch pretend play games on the video and then play the games. In a nationally tested study, they found that key literacy skills improved after the program was utilized. In addition, the majority of children continued to play the make-believe games on their own without adult intervention and teach the games to other children.

The building of empirical research on specific play interventions is encouraging and needs to continue. Future research should continue to identify the specific prompts and techniques that facilitate play. More randomized controlled studies with rigorous methodology are needed. Hopefully, these prompts and techniques could be adapted to a variety of settings and child populations. Dissemination of the scripts to parents and teachers for everyday use is an important next step.

Changes in the Culture of Play

Time for free-play has decreased over the past fifty years. Children are heavily scheduled for structured activities and the computer and videogames have taken over much of children's free time. The decrease in unstructured play time has occurred throughout the world. Children do not have enough opportunities to be involved in unstructured activities. The American Academy of Pediatrics, in a 2007 report, called for an increasing recognition of the importance of play in child development. However, even considering the shift in focus, [David Elkind, \(2007\)](#) suggested that children maintain the same desire to play. Although there are fewer spaces and less designated areas of play, children continue to play games and create learning experiences. They reinvent outdoor areas for make-believe games and change routine activities into games of finishing first or lasting the longest. Although it is difficult to generalize, it seems that many children continue to foster their creativity and problem solving through play.

Russ & Dillon reviewed play studies from 1986 to 2008 with different school-based populations that used the same standardized play task, instructions, and scoring system (Affect in Play Scale). They found that the organization of the play narrative and amount of affect expression has remained stable over this 20 year period. Imagination in the play narrative has significantly increased in recent years. These findings suggest that children are finding ways to develop abilities to express imagination and affective expression even though there is less unstructured time available to them.

Conclusion

Research supports the relationship between pretend play and creativity. Both cognitive and affective processes that are important in creativity occur in play and appear to be developed in play. The studies that are developing play interventions that facilitate play skills and creativity are crucial in expanding understanding of if and how play helps child development. Increasing sophistication of research design, measurement tools, and play facilitation techniques are necessary to move the field ahead. The study of the individual child is also important to include in researchers repertoire. Fein's study of master players continues to be a rich source of information and research ideas. If research evidence can continue to be built that play facilitates creativity and child development in general, then this finding will make a strong argument about the importance of play in order to influence social policy. In the meantime, children will continue to find ways to develop their imagination and find time to play.

As seen through the lens of creativity research, poetry is a multifaceted and complex domain. The importance of creativity in poetry may be best understood in the exploration of expert-level poets as opposed to studying a layperson's journey through what would be considered everyday poetry creativity. Instead, the observation of more eminent levels of poetic writing serves a greater purpose in many ways on gaining a full understanding of the scope poetry covers. First, understanding the functional process of writing poetry allows for a foundational knowledge of the nuanced process of writing poetry. Adding the intricacies of the creative process, allows the reader to see not only how it uniquely relates to poetry, but also how the poetic process sets a gold standard for the creative process.

Poetry itself is an elusively held topic in modern psychology. Experimental psychologists are often significantly more interested in the way the human mind invents or enters into narrative worlds (e.g., [Gerrig, 1993](#)) as opposed to how the mind produces poetry. The interest in poetry has tended to focus more on the nature of poets as opposed to poetry itself. This has led to comprehensive research about poets, particularly their rates of mood disorders. This association may very well originate from the idea that mind wandering is a key driver of poetic thought. Thus, it is an easy gateway to rumination, which is not at all uncommon among poets ([Kaufman and Baer, 2002](#)).

Poetry Through the Lifespan

In examining the development of poets, it is important to trace common patterns in lifespan and achievement. For example, in a study of 420 literary greats, the mean age of fiction writers to produce their best work was at 42.6 years old, whereas for poets it was 38.5 years old ([Simonton, 1975](#)). As a group, poets tend to peak at a statistically young age. Along with physicists, if poets do not create a major work by age 25, they are unlikely to ever do so. Further, poets produce double their lifetime output in their twenties as do their novelist counterparts ([Simonton, 2009](#)). Poets who began their journey by publishing their work at approximately 25 years old or younger statistically produce more poetry than those who begin their publication journey around age 30 ([Kaufman and Gentile, 2002](#)). Perhaps a better way to conceptualize these peak achievements is to look at what [Simonton \(2009\)](#) described as a poet's career age. He found that a poet's peak work occurs on average 20.1 years into their career (for comparison, a novelist's peak work happens around 27.1 years).

An alternate theory argues that different types of creators peak at different ages ([Galenson, 2005](#)). In one life cycle, early conceptual creators (or finders) enter prominence within their domain via a massive burst of greatness. In the life cycle of seekers, creators find their peak later, making contributions over a broad body of work. [Simonton \(2007\)](#), however, found historiometric evidence that the domain (in his study, poetry vs. fiction) is equally important in predicting when a writer will peak.

The Poetic Mode of Thought

The creation of poetry is ingrained in processes that are distinctive from processes that are more typical in science-driven or narrative styles of writing. [Bruner \(1962\)](#) coined the distinction between the paradigmatic and the narrative modes of thought. The paradigmatic mind is interested in objectivizing; the narrative mind is interested in subjunctivizing. Yet that distinction does not capture what is specific about the poetic mode of thought. Poetry also involves subjunctivizing, yet it deals with intentionality in a different fashion. That difference was well expressed by Auden when he noted, "[l]anguage is prosaic to the degree that 'it does not matter what particular word is associated with an idea, provided that the association once made is permanent'. Language is poetic to the degree that it does matter" (1990, p. 35). In summary, the main differentiating factor is how narrative and poetry deal with the issue of intentionality. Narratives express intentionality through characters; poetry expresses intentionality through language. That said,

as Borges noticed, in its origin, poetry is engaged with the telling of a tale (i.e., with a narrative) such as “the tale of Troy, the tale of Ulysses, the tale of Jesus” (2000, p. 47).

In order to express intentionality through language, poetry engages two senses: the auditory and the visual. As Hollander stated, “poetry is a kind of music, as it is a mode of picturing in the context of the eye” (1975, p. 3). Creating poetry involves (among other components) meter, rhythm, and rhyme. Principles regulating meter in poetry depend upon the arrangement of syllables and accents in each verse. Some poems are created with syllabic meter (i.e., according to the number of syllables), others with accentual meter (i.e., according to the number of stressed syllables), and others with accentual-syllabic meter (i.e., according to the alternation of stressed and unstressed syllables such as English iambic lines. Although not adhering to a strict meter, free verse also requires some sense of rhythm.

In fact, there are many ways a poet can create rhythm, before meaning is even contemplated. Hollander mentions “syllable sequence, stress pattern word boundary, modulations of stress pattern because of phrase grouping, additional prominence to syllables being given by internal rhyme, assonance, or alliteration” (1975, p. 33.) Hollander noticed rhyme has mnemonic, schematic, musical, and semantic effects. Yet the building blocks of a poem are not only based on its oral/auditory qualities. Hollander said that “the poem in the eye as a kind of picture, and one of the things we do when read a poem is to discern visual structures, to make out parts, wholes, relationships to see patterns in sub- and total contexts, and so forth” (p. 246).

The primary visual structures of a poem are its lines and stanzas. Beyond lines and stanzas, some authors took this visual component to extremes such as Apollinaire in his calligrammes or Augusto de Campos in his concrete poetry. This visual component is particularly important in Chinese poetry, where calligraphy plays a central role as a particular art bordering painting.

In the functional writing of poetry even minor changes in the visual and auditory components used in a poem can lead to a large transformation of meaning. In poetry writing, this linguistic importance lends itself to understanding its auditory and visual component. As language is an integral part of conveying meaning, so are rhythm and the text’s visual arrangement. In the writing process, a poet not only delivers a specific message but also produces an accompanying rhythmic voice, which in turn has to be placed in print. So, poetry is an oral art represented in print. The poet is, partially, both a composer and a painter. And, mostly, a language whisperer. As Pinsky (1998) stated, “Poetry is a vocal, which is to say a bodily, art. The medium of poetry is a human body: the column of air inside the chest, shaped into signifying sounds in the larynx and the mouth” (p. 8). That said, those sounds are conveyed visually.

Creative Process of Writing Poetry

In any form of writing, a challenge all authors and scholars face is the challenge of keeping the mind focused on a given task. The act of writing, especially in conventional styles, taxes a large portion of the mind’s working memory resources and other cognitive activities. The main processes involved in writing are planning, translating and producing text, and reviewing, acting as three interactive processes (Kellogg, 1994). To add to this mental taxation, this interaction also involves dealing with problems in different mental spaces. That is to say, distinct dimensions of language including grammar, semantics, and pragmatics must interact and develop coherently. Mature writers are easily able to take rhetorical needs into consideration when solving content issues, and vice versa when dealing with the reverse (Bereiter and Scardamalia, 1987).

Writing has specific qualities that pertain to the domain of creativity. Runco (2009) said that, first, “one way to describe writing’s unique advantage and benefit is in terms of the amount of detail and exploration allowed by writing” (p. 185); and, second, that “writing is best described as a process than a product, and may be that very process that benefits the writer” (p. 188). That rings true for all forms of writing, but it is particularly true of poetry.

In fact, Bruner used the writing of a poem to exemplify the nature of the creative process: “You begin to write a poem. Before long it, the poem, begins to develop metrical, stanzaic, symbolical requirements. You, as the writer of the poem, are serving it – it seems” (Bruner, 1962, p. 25). It is notable that Bruner called that process *freedom to be dominated by the object*. This freedom to be dominated by the object is what gives mind wandering such powerful role in the process of poetic meaning making. Thus, the act of writing and composing poetry serves to epitomize the nature of the creative process in writing. In conventional writing, defocusing attention may detrimentally negatively impact this process. However, in poetry, mind wandering is a skill employed by expert poets. Poets must be disposed to allowing for an active suspense of focus, mindfully wandering to allow language to fall into place and settle in a perfect form, both orally and visually (Preiss and Cosmelli, 2017; Preiss, 2019).

The uniqueness of the generative process of poetry may lie in the suspension of attention that is so dominant in other forms of writing. After a poet initially generates a basic idea for a poem, traveling inward to find a theme, the ability to productively mind wander defocuses the mind’s attention to the obvious task. In this way, mind wandering can be pointed out as one of the main components that defy the mainstream notion of expert level writing. In poetry, the initial planning stage is less clear-cut, challenging the idea that planning is a necessary step in producing a text. And yet revision ends up playing a prominent role in poetry; it allows for the correction of the natural aesthetical excess mind wandering calls for.

One of the biggest challenges a poet faces is to produce novelty, a paradigmatic signature of creative behavior. Although the combinations allowed for language are infinite, there are just enough patterns in the world to be sung, as Borges (2000) stated. A countless number of poems have been composed about a countless number of subjects, and it is up to the creative poet to find themselves outside of the current body of work. It is unsurprising that Rilke said in his letters to a young poet: “Do not write love poems.” (2011, p. 31) As one can imagine, love has remained one of the central subject matters in poetry. As a poet, if you want

to say something new about love, you also have to deal with the entire history of poems pertaining to the subject. Many others before this point in time have found his or her own voice, and the poet must do the same for their own voice and originality both among his or her forerunners and his or her contemporaries. [Borges \(2000\)](#) thought that although hundreds of metaphors could be invented in the search for originality, poets deal primarily with a few patterns behind those metaphors.

Recently, four distinct steps were identified in the process of creatively writing poetry. Briefly, these steps are: acknowledging extended time, developing trust in incubation, incorporating the creative process as a part of identity development, and recognizing the positive impact of creativity on overall well-being ([Preiss and Cosmelli, 2017](#)). Acknowledging extended time refers to the idea that creative writing takes an extended amount of time both on and off task. Second, trust and incubation refers to the idea that poets develop a sense of strategic mind wandering. "Acknowledgment of the role incubation plays on creativity is part of the process of building a self continuously engaged with the creative process." ([Preiss and Cosmelli, 2017](#), p. 306). Chilean poet Veronica Zondek said clearly:

If I don't write, I review what I have written; if I don't review, I am reading something that is close to it; I relate to what I am doing but not necessarily through writing... On the other hand, I have learnt to use those lapses of time such as when I am in the subway, the night, moments between work, between gardening or putting things in the oven.

Quoted in [Preiss and Cosmelli](#), p. 307.

Third, seeing the creative process as identity development is based on the idea that poets write because they intrinsically feel that they must write, which is consistent with the view that authors such as Rilke had about the act of being a poet. Rilke said:

There's only one way to proceed. Go inside yourself. Explore the reason that compels you to write; test whether it stretches its roots into the deepest part of your heart, admit to yourself whether you would have to die if the opportunity to write were withheld from you. Above all else, ask yourself at your most silent hour of night: *must I write?* (2011, p. 30)

Finally, the fourth step notes the understanding that the writing process is an extended process aiding in understanding how writing gives authors a set sense of closure. These four steps are linked by an extended process of mind wandering around a singular topic, immediately followed by the more focused attentional state in the process of revision.

A key point in the psychological view of creativity is that the creation of poetry is, in its nature, a life-time commitment. Even when a poet is not producing a text, it is instinctual to be naturally mind wandering about writing. In this way, as [Preiss and Cosmelli](#) suggested, poetry is the most intensive version of the creative process; the poet is always writing, even when they themselves believe they are facing writers block. Eminent poets are in a permanent state of searching for poetic insights, which often blurs the line between artistic and vital. In what is called the years of silence in the development of expertise, poetry takes on a very unique nature ([Weisberg, 1999](#)).

Poetry and Mental Health

Even within different creative domains, specific subgroups can differ widely in their rates of mental illnesses. For example, as measured by suicide attempts, hospitalizations, or periods of depression (as described in a brief biography), eminent female poets were found to be significantly more likely to suffer from mental illness compared to female writers in other domains (fiction, playwrights, non-fiction) and male writers in any domain. They were also more likely to have a described episode of mental illness compared to women in other eminent areas, such as acting, politics, and business ([Kaufman, 2001](#)). This finding became known as the "Sylvia Plath Effect." In additional studies, it has been found that eminent poets were more likely than other domains of creative writers to be mentally ill and show cognitive distortion ([Thomas and Duke, 2007](#)).

The healing power of narrative writing may be what is responsible for the Sylvia Plath Effect ([Kaufman and Sexton, 2006](#)). The creation of a story is the pivotal component of the healing effects of writing; yet as previously mentioned, poems do not carry the same narrative importance as other types of writing. Poems do not necessarily tell stories with a beginning, middle, or end, whereas most plays and stories do. As a result, there is little evidence as to why poetry would have similar benefits to other types of writing. For example, one study had participants either write a Haiku poem or a narrative over different occasions. The people who wrote narrative were less anxious and depressed, whereas there was no effect on the Haiku group ([Stephenson and Rosen, 2015](#)).

One line of research looks at how the actual linguistic distinctions writers use can be consistently associated with mental health. Suicidal poets are more likely to use words highly associated with the self in their poetry, whereas non-suicidal poets use collective language ([Stirman and Pennebaker, 2001](#)). This tendency is indicative of an inward focus as well as a lack of social integration. For example, linguistic patterns of eminent writers displaying bipolar behaviors used more death related words than the population showing unipolar patterns of behavior; unipolar writers were less likely to use self-related words than the normative population ([Forgeard, 2008](#)).

Conclusion

Writing poetry is not only about creating poems. It involves also dealing with the creative potential of a conscientiously unfocused mind so it can reach the required attentional disposition that enables the writer to produce new metaphors about universal themes. In so doing, the poet must deal with both the oral and visual components that give shape to a specific poem. The multiple combinations allowed by these components (in different linguistic and cultural traditions) is what gives poetry its incredible generativity. The translation of poetry was not addressed here yet the challenges poetry poses to translation rest on the fact that each language has its specific oral and visual qualities. Poets become true geniuses when they convey a universal message notwithstanding working with culturally specific material. At the end of the day, it is the creative process what makes all literature meaningful and universal. Poetic meaning making through the conscious use of our disposition to mind wander rediscovers and reinvents continuously the aesthetic powers of language.

Glossary

Bidirectionality Causal relationships that work in two direction, with A sometimes causing (or influencing) B, but other times B sometimes causing (or influencing) A. Bidirectionality has been uncovered in many studies of creativity.

Periodization of Influence The expression of creativity may vary from era to era, and sometimes the changes are regular and follow a pattern. It has been called “the clockwork muse.”

Paradigm shifts Thomas Kuhn’s idea that science progresses incrementally but at some point assumptions are questioned and there is a radical paradigm shift where those assumptions are rejected and often a new worldview is introduced.

Hidden Variable Problem Sometimes two things are correlated but not causally related because they both depend on some third, hidden variable that is actually the causal factor for both manifest variables. The correlation is, then, misleading.

Individualism A philosophy and ideology which respects individuality. That individuality is associated with autonomy and creative expression. Individualism and creativity are also associated with Liberalism.

Psychological Freedom A condition in homes, schools, cultures, and nations which allows authentic self-expression and thereby creativity.

21st Century Skills Creativity, Communication, Critical Thinking, and Collaboration. Research shows that creativity is the least supported by the Federal government, at least in terms of grants given.

Introduction

This *Encyclopedia* chapter reviews research that suggests relationships between politics and creativity. The plural, relationships, is vital, for although the research is scant, various associations are suggested, not just one. In fact, several of the connections work in one direction, with human creativity influencing what politics are offered and endure (i.e., the creative ones), but other associations suggest the opposite causality, with political situations determining how creativity is identified and supported—or not supported. This *bidirectionality* should not be much of a surprise because it also characterizes economics and other macro-level influences on and results of creativity (Runco, 2014).

This chapter reviews examples of how politics influences creativity, and examples of how creativity influences politics. It first extends the idea that the relationships between politics and creativity are complicated. These complications must be identified before the specific relationships are identified. Those relationships between politics and creativity only make sense once the complications are recognized.

It may be easiest to begin by describing the influence of creativity on politics. Several volumes, including *American Creation* (Ellis, 2007) and *A Great Improvisation* (Schiff, 2005) help with this sort of thing, the idea being that the American Democratic Republic was itself a result of creative efforts. Other specific political products which resulted from creative efforts can easily be listed, including the US Constitution and the Magna Carta. Research has pointed to political speeches as creative artifacts, as well. Katz-Buonincontro (2012), for example, quoted speeches by Barack Obama and Bill Clinton to illustrate. This line of work is justified by respected methodologies which were developed to examine the creativity of all kinds of verbiage (Runco et al., 2015). In fact the well-known theory of language put forth by Chomsky (1966) implies that all language is creative. People use a finite set of rules to generate meaning in an original fashion (i.e., saying something they have never said before) just about any time they open their mouths, or at least regularly. Consider next the political method often called “spin.” Here information with one meaning or implication is altered in a creative way such that the negative connotation is less apparent and a more pleasing message is more readily apparent. When “spin” hides factual information and does damage, it would certainly qualify for *malevolent creativity*.

The other direction of effect may be more important. This has political conditions and decisions influencing creative efforts and creative behavior. A number of scholars have considered this direction of effect. Seitz (2003), for example, examined this possibility and concluded that creativity and self expression, as well as entrepreneurship, varied with the distribution and redistribution of power and resources. He identified copyright restrictions, corporate control, and religious and political censorship as influences.

Note his inclusion of entrepreneurship. This is important because politics does not just influence creativity. It influences various things, including innovation, entrepreneurship, and various forms of self-expression. Also interesting is that Seitz referred to a *periodization* of influence, a term that refers to creative expression as it varies and cycles through history. A periodization of creativity described earlier in Colin Martindale's (1990) *A Clockwork Muse*. Similarly, periodization plays a central role in Thomas Kuhn's theory of paradigm shifts (i.e., periods of normal science and then revolution).

The relationships of politics and creativity are even more complicated than bidirectionality may suggest. What was just presented suggests two directions of effect, with creative individuals producing creative political products (e.g., speeches, policies, documents such as the Magna Carta, and even sound bites which are nothing but "spin") as well as political conditions influencing how creativity is expressed and supported. Further complication is indicated by the possibility of a third causality where both creative expression and politics are influenced by some other underlying variable. This should really come as no surprise, given how often the same thing has been found in a wide range of correlational research. It even has a name: "the hidden variable problem." It is a problem because correlational research is designed to uncover relationships. They are not causal relationships. They are just associations with unknown causality. Even if there is a high correlation, one of the variables involved could be causing the other (A causing B), but it could be that the opposite is true (B causes A). The correlation does not indicate which causes which. In fact, there could be a third hidden variable that actually causes both (C causes both A and B) and thus A and B are not actually causally related at all! Instead they both depend on the third variable.

This sort of thing was implied by the theory of Karl Marx. Runco (2014, p. 306) quoted Marx as saying, "art and politics are the surface manifestations of the same underlying social order." In this light there is some underlying social order, which may be related to cultural values or some broad ideology, and that social order in turn leads to artistic expression (one kind of creativity) but it also independently leads to political situations. Perhaps more clearly are the philosophies that also operate as hidden variables, influencing both creative expression as well as manifest politics. Seitz (2003) seemed to be aware of the interplay of cultural values and political policies when he described how

A theory of government and society that became increasingly influential in the 17th century, liberalism, created the conditions for individualism. These conditions are currently demarcated in contemporary Western democracies according to three premises. The first premise requires that all citizens receive equal treatment and consideration, independent of any particular conception of what is an acceptable lifestyle—that is, one either advocated by state ideology or formal government intervention. Similarly, the second and third premises set the conditions for individualism by endorsing both representative democracy and a market economy, as these promote the economic and ethnic equality of all citizens Thus, by institutionalizing fair and equal consideration of the needs of all citizens within a system of market relations and political representation of the people's will, liberalism fosters creative production by encouraging individual creative expression. (pp. 389–390)

This points clearly to the connection of liberalism and individualism goes a long way to explaining why individualism supports creativity. Individualism allows individuality; and individuality and its correlates (e.g., autonomy, independence, nonconformity) play an important role in creative effort because creativity depends on originality, and originality assumes that the person has done something that is unique and different from what others have done. In sum, the originality that is the basis for creativity is possible and perhaps encouraged in Liberal political conditions.

Political Liberalism

There various reasons to look to Liberalism as the philosophy that is the most likely to support creative expression. These reasons show that it is not an apples-and-oranges sort of thing, either, where one kind of creativity is associated with Liberalism and another kind associated with Conservatism. Instead, creativity is more likely in a Liberal society, and conventionality and conformity more likely in a Conservative society. There is a functional connection between Liberalism and creativity such that the latter is supported, and a functional connection between Conservatism and conventionality such that the latter is supported. These functional connections are logically and theoretically apparent, and supported by empirical data.

Ferris (2010) went into great detail about the connection between Liberalism and creativity. He explored the logical connection, which is compelling, but he also offered support by examining various historical eras and famous creators. Holland represents one of many fascinating and convincing examples. . As Ferris (p. 63) described it,

The Dutch were the architects and beneficiaries of what would be known as their Golden Age (1609–1713), an era during much of which Holland was pretty much the freest—and per capita the wealthiest and most creative—nation in the world. The Dutch dominated world maritime trade.... They counted among their philosophers immigrant freedom seekers like Descartes; the liberal skeptic Pierre Bayle, whose *Historical and Critical Dictionary* of 1697 would find its way into Thomas Jefferson's list of the 100 books vital to establishing the American Library of Congress; and now John Locke.

The phrase "wealthiest and most creative" is of obvious importance to the present chapter, but note also the various domains that are mentioned in that quotation, including maritime trade, which led to the founding of New Amsterdam (New York), a huge commercial success, as well as philosophy. But the benefits of Liberalism are even broader. Again quoting Ferris (2010, p. 64),

The Dutch innovated oil painting [and] created new styles of painting as well, influenced in part by the use of optical devices such as the pinhole camera, the refracting or 'Gali-lean' telescope, and lenses which could project an inverted image onto a blank canvas. One such projector is thought to have been developed by the naturalist and microscopist Antoni van Leeuwenhoek and employed by Johannes Vermeer, both of whom worked in Delft.

Dutch artists expressed their appreciation of Liberalism in the sense that "Dutch paintings celebrated freedom, industriousness, and prosperity" (p. 64). Note the recognition of the benefits of Liberalism for science, as well as for art, and the idea that Dutch artists took advantage of scientific innovations.

Ferris (2010) elaborated on the fact that the Liberalism of the Dutch had great influence on John Locke, "architect of the Enlightenment." More concretely Locke was author of *Letter Concerning Toleration*, *Essay Concerning Human Understanding*, and *Two Treatises of Civil Government*. Locke's thinking directly influenced the Framers of the US Constitution. Ferris describes dozens of other historical examples and case studies showing the benefits of Liberalism, many for creativity and individualism.

An important part of Liberalism is freedom, which of course is at the heart of many governments and thus an important political concern. Freedom is a useful term in this chapter because many studies have supported the role of *psychological freedom* in creative efforts. Frank Barron was quite clear about the benefits of psychological freedom for creativity, as is especially clear in his volume, *Creativity and Personal Freedom* (1968). Empirical studies have also supported the benefit of psychological freedom for creativity, including those of Harrington, Block, and Block (1987). They examined how various parenting styles provide children with more or less freedom and how optimal freedom seems to support children's creative thinking. This line of work tests earlier work by Carl Rogers. A critical concept in Rogers' thinking was "unconditional positive regard," which he explained as providing individuals with respect so they were free to be themselves and to be spontaneous and creative.

This discussion has not drifted from the topic of politics. The previous paragraph or two merely explores specific benefits of Liberalism and any political support for individuality and freedom. These benefits are apparent on all levels, including societal, familial, cultural, and individual.

Voting and Creativity

Some governments allow voting, and several empirical investigations have examined voting as it is related to creativity. This research is fairly rigorous as well as empirical and has direct implications for the discussion of creativity and politics. There is an important assumption in this research, namely that creativity is expressed in invention. This is an easy assumption to accept, though certainly there is more to invention than just creativity. This is especially true when the measures of invention used in the research focus on patents, for those would require knowledge about the patent system as well as creativity. Still, it may be impossible to obtain a patent without some creativity. As a matter of fact the requirements for a patent are remarkably similar to the dimensions of creativity found in the work of Simonton (2012) and others. These include novelty (or originality), utility (or effectiveness), and surprise. No wonder research often does look to patents as a concrete expression of unambiguous creativity.

Some of this research is directly relevant to the present discussion because it has examined how patents are related to voting patterns. In one investigation McCann (2011) looked at the voting patterns of the two US Presidential elections involving the 43rd President, George W. Bush. McCann started by classifying every state in the US as "blue" (Democrat) or "red" (Republican). Although this is a big generalization, given that many voters in a red state actually vote democrat, and many voters in blue states actually vote republican, the Electoral College system used in United States makes similar generalizations (Subsequent research, summarized below, avoids this generalization). McCann also obtained data from the US Patent and Trademark Office about the number of patents granted in each state. Come to find out, there were significantly more patents granted in blue states compared to red states, even when various statistical controls (e.g., degrees of urbanization, SES, and IQ) were included in the analyses. McCann's conclusion focused on the fact that red states tend to be more conservative, and blue states more liberal. In addition to the benefits of Liberalism for creativity mentioned above, there is also the fact that Conservatism by definition tends to protect the status quo and avoid change. This in turn could easily minimize creativity because creativity always introduces something new.

McCann (2011) also reported data from a project where 141,000 households were telephoned and various personality traits estimated. This indicated that Openness was related to the number of patents awarded, which makes a great deal of sense given that Openness is the personality trait that is associated with creativity more than any other trait.

Runco et al. (2017) extended this research but offered a more fine-grained analysis. Instead of looking at state-level voting, they obtained county-level data, which meant a much larger sample size (over 3000 counties rather than a mere 50 states) and, as a result, more robust analyses. Their voting data were from the 2016 (Hillary Clinton versus Donald Trump) election. But their results quite similar and, like the previous work by McCann (2011), showed blue states to have significantly more patents granted than red states. The control variables included educational level, socioeconomic status (SES), income, and diversity within each county. Two metrics were found in the US Census data that allowed examination of diversity. The first was *racial diversity* and based on a ratio of individuals, within each county, who chose two or more races when taking the 2015 Census. Linguistic diversity was also based on US Census data (online). It reflected the proportion of homes, within each county, where some language other than English was spoken. Findings indicated that the number of patents granted within counties was negatively related to Conservatism and positively related to educational level and racial diversity. The finding about racial diversity is no surprise, given theory and research

that diversity of various kinds is beneficial to creativity. The finding about Conservatism is consistent with other results, summarized above, showing a positive relationship of creativity with Liberalism and a negative relationship of creativity with Conservatism.

Conclusions

Several kinds of data were summarized in this chapter, including those reviewed last and based on voting patterns and the number of patents granted (as an index of creativity). This entry began with a summary of relevant case studies and the historical analysis of Ferris (2010). Admittedly case studies by themselves have limited generalizability, but in the present case they are consistent with the other more experimental data. In fact there are other data suggesting a relationship between political conditions and creativity. Simonton (1984, 1997), for example, looked to various events, including international war, civil disturbance, and political instability, as indicators of particular political conditions. Each of these events was, at different times through history, associated with estimates of creativity and productivity. Zysberg and Schenk (2013) examined political orientation and creativity and reported that both social and political attitudes were associated with creative potential.

One convincing explanation for why political policies are related to creativity and its correlates points to resources. Policies determine how resources are allocated, and apparently Liberalism tends to allocate resources such that creativity is supported. With this in mind Abdullah and Runco (2018) decided to compare the frequency with Federal grants are awarded to creativity, in comparison to how many grants are awarded to other similar topics, such as scholastic achievement and general intelligence. They looked to data about awards given by the National Science Foundation (NSF) and Institute for Education Sciences (IES) from 2005 to 2016. Awards for creativity research were compared with awards given to the other three 21st Century Skills, namely collaboration, communication, and critical thinking. Results indicated that creativity was supported least of all four skills. Both agencies funded critical thinking with regularity. The NSF also funded collaboration with some regularity, and IES funded communication, as well as critical thinking. This research may exemplify how policy leads to the allocation of resources, but it may also be a reminder that creativity is not easy to operationalize. Creativity is one of the 21st Century Skills, but it is not funded as well as the others, perhaps because grants require good operationalization and evaluation, both of which might be undermined by debates about how to best define and measure creativity.

This possibility may be added to the other complications, mentioned early in this chapter, which lead to difficulties in studying how politics is related to creativity. These included the ambiguous causality, and possible bidirectionality, as well as the possibility that apparent causal relationships actually reflect hidden variables. Certainly much is difficult to operationalize when studying both politics and creativity. Given that politics may determine how resources are allocated and thus determine whether or not creativity is supported, more research on this topic is warranted.

Introduction: Defining Polymathy

According to the Oxford English Dictionary, “polymath” originated in the early 17th century to designate a person of wide knowledge or learning. Since that time, the term has often been linked with “Renaissance man” and with the idea that the wide knowledge be used for some practical purpose or integrated in some effective way. The apparently minor differences in these two understandings of polymathy have important consequences for creativity studies, and both leave key aspects of the phenomenon unresolved. To begin with, should passive knowledge be enough to qualify a person as a polymath? One of us once met an individual who had acquired twenty-three master’s degrees. As he himself admitted, he never used his knowledge practically; he simply loved to learn. By one definition, this man was a polymath; by the other, not. What, then, is the relationship between breadth of learning and productive outcome and creative productivity.

Other issues left unresolved by competing definitions of polymathy concern impact and incidence. Some creativity scholars have suggested that only individuals achieving eminence in multiple disciplines, in the manner of Hildegard of Bingen, Leonardo da Vinci, Andreas Vesalius, Maria Gaetana Agnesi, Benjamin Franklin, or Sofia Kovalevskaya, should qualify as polymaths. Advocates of this position argue that polymathy is rare, not least because today’s rapid expansion of knowledge, intense scholarly competition, and deep disciplinary specialization militate against mastery of more than one domain or field of endeavor. However, other scholars place the bar for impact much lower, suggesting that polymathic ability is not only common, but teachable. Does either position—or both—best capture the polymathy-creativity connection?

To address these questions, Root-Bernstein and Root-Bernstein proposed that, in certain circumstances, polymathy might indeed be qualified as creative, and that creative polymathy be defined as “active engagement in multiple interests or endeavors that draw upon or synthesize vocations and/or avocations, simultaneously or serially, across the lifespan.” Distinguishing between polymathy and creative polymathy leaves open the possibility that individuals (such as the multi-masters-degree holder mentioned above) might be polymathic without being creative. The converse, however, is problematic. If one understands creative problem-solving as the integration of two or more ideas, methods, concepts, principles, techniques, or materials in a novel and effective manner, it is not possible to be creative without being in some measure polymathic.

Moreover, to say that the creative polymath must be “actively” (rather than “productively”) engaged expands the notion of what that measure might be. Individuals may play and compose music without ever performing publicly; they may learn mathematical methods without ever inventing new problems or proofs. Yet these private activities can develop skills and understandings useful to the polymath’s public contribution in other disciplines. Hjerter (1986) and others find, for example, that many successful poets, novelists, and playwrights have been “Sunday painters” or “closet artists” who purposefully used their artwork to explore ideas that informed their writing. Eliminating the need to be publicly productive in all endeavors opens the door to amateur pursuits carried out intensively over long periods of time as qualifications for creative polymathy (See AVOCATION, this volume).

The Relationship Between Avocation, Breadth of Interest, and Creative Accomplishment

Avocational activity has long been associated with eminence. Over 150 years ago, Galton noticed that British “geniuses” and members of the Royal Society tended to have multiple mechanical, musical, literary, dramatic, and artistic hobbies. Van’t Hoff (1878) concluded from a convenience sample of over two hundred scientific biographies that what distinguished the most creative scientists from their less successful colleagues was imagination “manifest[ed] in ways other than their researches.” These manifestations included arts and music, as well as philosophical and religious writings. In the early 20th century, similar results were reported for scientific and mathematical ability by Ostwald in his book *Grösse Manner* (1909) and Mobius in *Ueber die anlage zur mathematic* (1900). Beyond the sciences, Cox (1926) and White (1931) concluded that what differentiated the genius from

more average peers was “versatility.” In White’s words, “range of interests is not the same as range of ability and we need both components to make our point! ... [h]e surpasses him in range of ability” (1931, p. 482). [Raskin \(1936\)](#) and, more recently, [Simonton and Cassandro \(2010\)](#) confirmed that an adaptable range of interest is a direct correlate of eminence.

Avocational activity or versatility is not limited to the eminent, however. [Milgram et al. \(1997\)](#) studied career success among several thousand Israelis and found that the single best predictor was having one or more mentally challenging avocations practiced over extended periods of time. Root-Bernstein and colleagues have generally found that acquisition of training in more than one discipline, either formally or informally, appears to be reasonably common (see Part III, below). What differentiates eminent individuals from others is not the polymathic interests per se, but the influence of extra-professional interests on professional purposes. In a study of 38 scientists, [R. Root-Bernstein et al. \(1995\)](#) found that the eleven most eminent among them (all Nobel Prize winners and/or members of the U. S. National Academy of Sciences) spoke of utilizing their avocational interests to generate novel ideas and stimulate their vocational creativity. In contrast, the twelve least successful scientists in the cohort uniformly described their non-scientific activities as regrettable wastes of time to no vocational effect.

As [Dewey \(1934\)](#), [Gruber \(1988\)](#), and [Root-Bernstein \(1989\)](#) have independently argued, the creative polymath sets him or herself apart from others by the purposeful integration of interests, respectively referred to as an “activity set,” a “network of enterprise,” or “correlative talents.” Gruber has documented perhaps the most extraordinary example of interest integration—that of Charles Darwin, who networked geology, geography, zoology, botany, paleontology, animal husbandry, agriculture, anthropology, and psychology into a unified theory of evolution by natural selection. Similar observations of creative activity sets have been made about Herman von Helmholtz and the dozen other German scientists who founded the 1847 Biophysics movement by [Crane \(1966\)](#), who documented a direct correlation between the number of different scientific, philosophical, and cultural interests each scientist had and how many fundamental contributions they made to the newly unfolding science. His study, as well as Gruber’s, suggests that creativity may be fundamentally combinatorial, an argument first proposed by Ostwald: the greater the range of problems, ideas, principles, methods, materials, and processes that an individual actively integrates within a personal network of interests, the greater the potential for creative outcome.

A combinatorial understanding of creativity might explain apparent conundrums such as simultaneous discovery or general creative ability. [Simonton \(2004\)](#) explains simultaneous discovery as a random, stochastic process. A closer look often reveals that simultaneous discoveries and inventions arise from polymathic individuals with similar training and interests working on shared problems or challenges ([Root-Bernstein, 1989](#)). From a combinatorial perspective, each of an individual’s interests need not be expressed separately in public forms of productivity, but will be integrated into the creative outcome of the polymath’s efforts.

The previous conclusion is something of a contentious point, since polymathy and general creative ability are often conflated. [Kaufman and Baer \(2004\)](#), for example, ask whether the physicist Stephen Hawking might have devoted himself to music or the singer Madonna might have taken up mathematics to creative acclaim equal to that of their first vocations. The two scholars advised Hawking and Madonna to stick with what they knew best. Strikingly, the career choices made by some contemporaries contradict Kaufman and Baer’s counsel. Consider the case of the child actress Danica McKellar, who starred in the television series “The Wonder Years.” McKellar earned an undergraduate degree in mathematics at UCLA, where she coauthored a paper that introduced what is now called the “Chayes–McKellar–Winn theorem.” She currently writes best-selling mathematics books while continuing to perform in television and film. Similarly, rock star Brian May took some thirty years off from a doctoral program in astrophysics to perform as singer, songwriter, and guitarist for the band Queen. Now considered a leading authority on cosmic dust, he has recently collaborated with NASA on the New Horizons probe into the outer reaches of our solar system.

With combinatorial creativity in mind, the question is not whether McKellar and May prove equally productive in all their endeavors, but to what extent their “expertise” in breadth speaks to the transfer of ideas, techniques, and/or processes from one field to another within their networks of enterprise. Consider the Nobel Prizewinning economist Herbert Simon, who made fundamental contributions to political science, philosophy, cognitive science, and psychology while also practicing hobbies including chess, piano playing, musical composition, drawing and painting. He was highly aware of the mutual reinforcements of avocation and vocation: “I can rationalize any activity I engage in as simply another form of research on cognition ...” he once said. “I can always view my hobbies as part of my research” (cited in [Frantz and Marsh, 2016](#), pp. 1–2). Indeed, it was Simon, in collaboration with Chase (1973), who formulated the well-known “ten-year rule” for mastering a new subject by studying how long it took him to learn chess. Although never a world-class chess player, Simon acquired enough *savoir-faire* in the game to connect it usefully to his professional research on decision-making. In Simon’s hands, creative polymathy led to the integration, not just of disparate interests, but of disparate areas of knowledge.

Differential Rates of Polymathy and Patterns of Creative Achievement

General considerations suggest that polymathy is not only associated with, but relatively common among the eminent. [Van’t Hoff \(1878\)](#) found that 26% of the scientists he studied displayed artistic inclinations. [Claparède and Flournoy \(1902/1904\)](#) found that 52% of the mathematicians they studied pursued a musical avocation. Taking a much longer view over 2000 years of Western history, [Gray’s 1966](#) study of 2400 eminent individuals reported that 19% made significant contributions to more than one discipline, even though scientific or technological fields of interest were omitted from review. [Cassandro’s 1998](#) study of 2102 creative

geniuses over the same time period found that 24% were eminent in more than one field (e.g., science and literature); another 15% were eminent in related disciplines (e.g. painting and sculpting or literature and drama).

Certain limitations of these studies—disregard of avocational activity or preferential attention to one or another field of knowledge and lack of rigorous controls—suggests that their overall results may very well under-estimate expressions of polymathy among the elite. As a corrective, Root-Bernstein and collaborators have taken a survey approach to documenting concurrent vocational and avocational engagement among both average and eminent groups of professionals. Self-reports of avocations and hobbies are correlated with vocational achievement measures such as numbers of papers published, patents granted, companies founded, citation totals, membership in a national academy, or the award of a Nobel Prize. The data are then compared with rates of avocational participation reported in census data or in windfall surveys of open enrollment groups, such as the 1937 survey of its membership by Sigma Xi, The Scientific Research Society.

In this manner, Root-Bernstein and collaborators have found that the eminent scientist typically engages in one or more adult arts, crafts, or performance-related avocations, whereas only one in three average scientists do so. Fifteen to twenty-five percent of all scientists have an adult music avocation, while 10%–15% have an adult photography avocation. Grouped by themselves, however, eminent scientists are 15 to 25 *times* more likely than average scientists or the average US citizen to have adult avocations involving visual and plastic arts, drama, creative writing, or crafts such as woodworking and metalworking (Root-Bernstein & Root-Bernstein, 2004; Root-Bernstein et al., 2008). Root-Bernstein et al. (2019a; 2019b), as well as Niemi (2015), observe that these types of correlations also apply more broadly to science, technology, engineering, mathematics and medical (STEMM) professionals most likely to produce patents, found new companies, or produce high impact scientific papers. Moreover, Root-Bernstein et al. (1993) found in one longitudinal study group that scientists winning the highest honors and having the highest impact measures (12 of 38 individuals, or 31%) worked across multiple scientific disciplines; in comparison, less successful scientists in the same group remained within the discipline in which they obtained formal training.

The present authors have undertaken a broader, as yet unpublished, study of Nobel laureates in literature, economics, and peace that extends comparison to additional professions beyond science and to general population controls from across the globe. By and large, the incidence of polymathy among these additional groups of eminent creators reflects that found among elite STEM professionals. Fifty percent or more of literature, peace, or economics laureates have demonstrated interests in two or more fields of endeavor. Sizeable proportions, ranging from 14.5% of Peace Nobels to 30% of Literature Nobels, engage in three or more fields. Despite common polymathic inclination, however, each group of laureates tends to favor different patterns of interest integration. Forty-four percent of laureates in literature, for instance, favor polymathic pursuit in the arts, whereas only 18% of economic laureates and 22% of peace laureates do. The latter two groups appear to prefer intellectual avocations in the humanities and social sciences or, indeed, the sciences. Dual or serial vocations are not uncommon. Gao Xingjian, literature laureate, has made his reputation as both writer and painter; Maurice Allais, economics laureate, also won acclaim as a physicist; Fridtjof Nansen, peace laureate, combined outstanding achievements as an athlete, scientist, explorer and diplomat.

In sum, Root-Bernstein and collaborators confirm van't Hoff's (1878), Claparède and Flournoy's (1902/1904) and Cassandro's (1998) finding that many eminent individuals become well-recognized in two or more related disciplines. Polymathy is highly noticeable among the elite in a range of fields; it is also reasonably common among working professionals, at least in the sciences and engineering. Root-Bernstein et al. (2013) document that about 60% of the STEM professionals they studied can, when asked, articulate specific ways in which they integrate diverse avocations with vocation. Over 80% argue that such integration is valuable to professional training. In combination with qualitative statements made by the likes of Herbert Simon, it becomes clear that polymaths generally recognize the purposeful choice and integration of multiple interests as key to their creativity.

Types of Polymathy

As must by now be clear, polymathy comes in different shapes and sizes. Burke (2010) has proposed four qualitative types of polymaths distinguishable by intellectual breadth and practice within and across disciplines.

1. **Passive polymaths**, who are broadly educated or widely read in many disciplines but actively engage in none, or work in only one. An example of a passive polymath would be the individual mentioned above who had earned twenty-three master's degrees in as many subjects, to no creative purpose.
2. **Limited polymaths**, whose activities cluster around closely related disciplines. Mozart and Picasso represent the type. Both stayed within well-defined fields of endeavor, yet explored every aspect, material, and technique of the music or art of their day, masterfully integrating diverse themes and methods and inventing new forms. As their examples make clear, a limited polymath can be extraordinarily creative.
3. **Serial polymaths**, who forge reputations in multiple disciplines one after another, often across fields. Gordon Parks exemplifies the serial polymath, one who broke through artistic silos as well as color barriers in 20th century America, a public success in all his ventures. He originally made his reputation as a fashion photographer and a documentary photojournalist before turning to poetry, autobiographical fiction, script writing, filmmaking, music composition and, finally, painting.
4. **Proper polymaths**, who make recognized contributions to several disciplines and/or fields simultaneously. Leonardo da Vinci remains the archetype, although modern exemplars such as MIT's Erik Demaine, a mathematical prodigy turned computer innovator, ground-breaking origami artist, and glass sculptor, reminds us, along with Herbert Simon, that such polymaths can still be found today.

Araki (2015) proposes alternative terminology, using “philosophical” rather than passive, “pragmatic” rather than limited, “ideal” rather than proper to describe polymathic types commensurate with Burke’s. Root-Bernstein and Root-Bernstein (2011) propose an alternative, developmental typology focusing on the evolution of polymathic practice over a lifetime. The six categories of developmental polymathy generally expand on Burke’s last three (those Araki terms “experiential” forms), leaving aside passive (philosophical) interests as non-creative. The limited (pragmatic) polymath, for example, may serve as an umbrella category for the following two developmental types:

1. **Early specialization followed by mature specialization.** In this instance, the essential training and work of the individual remains within a single field, but over time, the individual explores more of that field in increasing breadth and depth, integrating disparate elements within the discipline in new ways. Once again, Mozart and Picasso represent individuals specializing early and late. Another good exemplar is Paul Erdős, one of the most prolific mathematicians of the past century. Erdős contributed to virtually every type of existing mathematics, while also inventing several new sub-disciplines within the field.
2. **Early breadth followed by mature specialization.** Composer Elliot Carter exemplifies this developmental type, having obtained his undergraduate degree in English while simultaneously studying music and mathematics and then teaching the latter two subjects, as well as physics and Greek literature, at the college level. As his music career blossomed, he turned full-time to music composition. Notably, many elements of Carter’s mathematical and literary training are evident in his later music, suggesting that at least some of his creativity involved a continuing integration of his early diversified training.

The next two categories expand developmentally on Burke’s concept of serial polymathy:

3. **Early specialization followed by serial mature foci.** Former National Institutes of Health Director Harold Varmus exemplifies the type. An English major in college and a university newspaper editor, Varmus discovered an interest in science as a college senior and enrolled in medical school. Eventually he switched to biomedical research and, sometime after earning a Nobel Prize, he became a highly successful administrator.
4. **Early breadth followed by serial mature foci.** Roger Guillemin, devoted in his early years to drawing, painting, music, literature, and the sciences, fits this type. Choosing specialized training as a physician, he later turned to biomedical research and, like Varmus, won a Nobel Prize. Because of his early and continued interest in painting, however, he recognized the artistic potential of computer drug design programs used for his research. Eventually he retired from scientific research to become a full-time artist recognized as one of the founders of electronic art.

The final two developmental categories expand on Burke’s concept of proper (ideal) polymathy:

5. **Early specialization followed by mature breadth.** Sometimes creative individuals are recognized and groomed early for particular talent but find the time and inclination to branch out after they have established reputations in that primary field. Richard Feynman capitalized on his mathematical ability to become one of the youngest Nobel laureates in physics, a field in which he produced more highly cited papers in a broader range of topics than anyone ever before. As he reached middle age, however, he began steadily broadening his interests within and beyond science to include music (he played bongo drums at a semi-professional level), painting, computer sciences, nanotechnology (a field whose goals he defined), writing and many other scientific disciplines as well.
6. **Early breadth followed by continuous mature breadth.** One of the best exemplars of this type is Sofia Kovalevskaya, a late 19th-century Russian mathematician also recognized by her early twenties as one of the most significant poets and playwrights of her time. Likewise, the prolific African American inventor George Washington Carver was also a painter and a scientific popularizer throughout his life.

Creative Polymathy and the Ten-Year Rule

Whether classified by qualitative or developmental type, much about the creative polymath remains elusive, including why people adopt a wide-ranging approach to developing their talents in the first place. Many consider the polymathic strategy inherently difficult, especially when measured in creative impact on more than one discipline or field. Not only does it take some ten years, or 10,000 hours (on average), to master a discipline sufficiently to contribute to the field, it may take an additional ten years, so the argument goes, to contribute something truly creative (Kaufman and Kaufman, 2007).

These observations may be well established, yet they do not appear to pertain to creative polymaths, some of whom have contributed professionally to a wide range of disciplines in very short periods of time. Darwin is one example. His integration of some ten disciplines into the theory of evolution by natural selection—certainly one of the most creative scientific achievements of all time—should have taken more than a century to accomplish if the ten-year rule were inviolable, yet he managed it in thirty. Simonton and Cassandro (2010) point to Blaise Pascal as another individual for whom the ten-year rule seems inappropriate. Pascal died at the age of 39, yet within the 20-year span of his career made significant contributions to mathematics, physics, technology, philosophy, religion, and literature.

Clearly the 10-year rule can be broken. The question is how? Prodigies, by definition, master disciplines much faster and more efficiently than the average individual; polymaths appear to do the same, though they may not display obvious prodigiousness. Rather, polymaths appear to shorten their time to mastery using highly effective learning strategies. In *The Art of Learning*

(2007), the chess prodigy Josh Waitzkin details how he consciously adapted and transferred training techniques from chess to T'ai Chi Ch'üan, a competitive martial art, thus proving himself a serial, specializing polymath. Waitzkin won the U. S. Junior Chess Championship at age sixteen, after ten years of training. He won the world championship in T'ai Chi Ch'üan at age nineteen, after just three.

Yet another learning strategy works to abrogate the ten-year rule—ironically enough, the master game plan of Herbert Simon himself. Simon cautioned that “the ‘Renaissance Mind’ is not broader than other intelligent minds, but happens to cover a narrow swathe across the multi-dimensional space of knowledge ...” (Frantz and Marsh, 2016, 1–2). He himself specialized in on the problem of decision-making wherever it occurred, rather than specializing in a discipline or field. “What I am a monomaniac about,” he acknowledged, “is decision-making” (Frantz and Marsh, 2016). The creative polymath, his example suggests, does not so much master multiple disciplines as attend to specific sets of information, principles, or processes needed to address concerns across disciplinary boundaries. Polymaths are adept at a “take-what-you-need” strategy of learning instead of a “master-the-entire-field-first” approach.

Nurturing Creative Polymathy

If strategies of learning can enhance polymathic mastery and attendant creativity, are creative polymaths born or made? The answer may well be yes to both. In their review of existing neurobiological studies, Zeidán-Chuliá and Argou-Cardozo (2018) found that cognitive functions associated with acquiring and integrating diverse types of learning are under the direct control of specific genes—and therefore are inheritable traits. The evidence also indicates that these traits are susceptible to modification and augmentation by means of experience and education. Thus, Zeidán-Chuliá and Argou-Cardozo contend that polymathy is likely to result from a combination of genetic and environmental factors. In her qualitative study of thirteen contemporary polymaths, Cotallessa (2018) argued similarly that they were “born,” in that they displayed unusually broad interests and abilities from a very young age. They were also “made,” since most benefitted from familial or institutional support of their diverse talents. As Cotallessa concluded, “Polymathy develops due to a combination of nature and nurture, and polymathy is maintained in adulthood by a willingness to continue to work to improve oneself through self-directed learning” (2018, p. 1).

Today's specialized education rarely supports the polymath's need for multi-disciplinary training. For this reason, if no other, Zeidán-Chuliá and Argou-Cardozo (2018) warn, society may be hemorrhaging polymathic talent. Certainly, as Araki (2018) and others point out, in the absence of social and institutional support polymaths face unusual obstacles, not least professional marginalization. “To be a polymath,” Cotallessa (2018) has observed, “one must accept not fitting in the typical box and perhaps even embodying apparent contradictions.” Consider the case of Silas Weir Mitchell. A practicing physician and bench scientist who founded American neurology with fundamental contributions to toxicology, pharmacology, and psychiatry, Mitchell also produced a series of best-selling historical novels considered comparable to those of Thackeray and Hawthorne, giving rise to regular accusations of charlatany from those who doubted the clinical acumen of a doctor who spent so much time writing fiction.

Despite time and energy lost to the professional drawbacks, a case can be made that creative polymathy depends on outsider experience of some kind. Regarding Nobel laureates, Hollingsworth (2007) surmised that marginal status in terms of cultural tradition, religion or language may have habituated many individuals who eventually reached the top of their professions to high degrees of cognitive dissonance and complexity—two often-identified characteristics of creative thinking. The same habituation may well be true of polymaths negotiating ambivalent professional status—at least in terms of willingness to adopt adversarial and/or innovative viewpoints or to embark on transdisciplinary syntheses. Marginalized as a woman from a career in science, Beatrix Potter was no stranger to contrarian thinking when it came to her amateur mycological studies. Subsequently funneling her idiosyncratic training as a naturalist into her picture book writing and illustrating, she made outsized contributions to children's books in no small part by rethinking fictional conceptions of nature and animal nature.

It seems worth noting at this point that different types of polymaths appear to accommodate outsider status in different ways. If proper polymaths such as Weir Mitchell get criticized for pursuing disparate fields simultaneously, serial and limited polymaths rarely do. No one attacks Roger Guillemin for becoming a professional artist after winning a Nobel Prize in Physiology or Medicine and retiring from science. No one suggests that Picasso ought not to have drawn upon so many artistic cultures, nor explored so many media and materials within the visual and plastic arts. Breadth of interest may also be masked, as in the case of individuals like the philologist and secret fantasy writer J.R.R. Tolkien, by keeping avocations hidden from professional colleagues. That the polymathic path taken by any one individual may reflect personal and professional tradeoffs of many kinds begs further investigation, particularly with reference to creative outcome.

Whatever the role of marginal status, if the link between creativity and polymathy is as strong as many investigators make out, then modification of educational and workplace institutions systems in support of creative polymaths may be of great benefit to society at large. Universities, both as educational institutions and employers, often tout the creative benefits of transdisciplinarity, but are organized in disciplinary silos that militate against it. Historically, many individuals who have succeeded at transdisciplinary projects have done so with minimal or unusual institutional support. One could argue that Darwin succeeded as a polymath only because he was independently wealthy, insulated from institutional constraints. Einstein did his breakthrough work in physics while earning a living from non-professional work as a patent examiner, a common economic strategy among

creative artists, writers and performers. Can most proper or later-breadth polymaths succeed without institutions that support such freedom? Can universities and other institutions alter their organizations to be more integrative in support of such polymaths? This, too, is an area of great importance for future research.

The Future of Polymathy Studies

Whether one considers historical, psychological, social, or economic aspects of the phenomenon, so many issues in the study of polymathy remain unresolved that it seems appropriate to conclude by way of reiterating the basic questions.

First, is polymathy necessary for creativity? Is it truly the case that the more diverse the set of disciplinary tools, methods, principles, and problems an individual masters and integrates, the greater the number of new and important contributions he or she can make?

Second, how do polymaths come by this integrative ability? Is polymathy a consequence of nature or nurture or both? To the extent that breadth of interest can be learned, what is known about how different intellectual and developmental types of polymathy respond to different educational approaches, social supports and institutional organizations? Does it matter whether polymathic ability is developed through formal, informal or self-education? How, indeed, is early polymathic potential recognized? Researchers know almost nothing about these things.

Third, where is the bar placed for polymathic achievement? Is multiple domain contribution in fact the goal of polymathy or can the integration of avocations and vocations in the service of a singular creative contribution be an equally valid outcome? Are Picassos and Mozarts working within one domain actually doing the same thing as Helmholtzes and Simons working across several?

Fourth, are only certain people endowed with broad creative capacity or does everyone have the potential to be polymathic and, through polymathy, to achieve some degree of creativity? Can the creative potential of the general population be increased by fostering polymathic studies? Can current educational institutions even offer the transdisciplinary niches necessary to accommodate the needs of polymaths? Or would it take a transformation in education?

Finally, what are the psycho-social concomitants of polymathy? Do polymaths frequently experience professional marginalization because they are inherently different in their cognitive approaches to learning and creating? Or does their personal experience of outsider status promote polymathic ability? Would removing educational and professional obstacles to polymathy paradoxically destroy some critical goad to the polymath's creativity or would it lead, instead, to a social flowering of a new Renaissance, one capable of ameliorating the most pressing problems of today and tomorrow? In the face of so many uncertainties, one prediction seems certain: it will take a polymathic approach to the problem of creative polymathy to find resilient answers.

On the surface, there are few connections to be made between the well-established philosophical tradition of pragmatism and today's growing research literature on creativity besides some scattered references to pragmatist scholars who addressed, tangentially, creative expression (most famously John Dewey's seminal *Art as experience* from 1934). The pragmatist heritage in its depth, its views of the mind, of human action and society infuse past and present theories of and research on creativity. Pragmatism as a philosophical orientation has a lot to tell researchers about creativity today.

To start with, the notions of *value*, *appropriateness*, or *suitability*, which are embedded in classic definitions of this phenomenon, have clear pragmatist roots as they focus on the consequences of thinking, acting, and creating in the world. Second, the recurring idea that creativity requires some kind of *problem to solve* – vividly expressed in the creative problem-solving literature – has strong parallels in early 20th century pragmatist accounts of how thinking emerges out of encountering and dealing with obstacles. Most critically, there are the less visible yet hugely consequential debates that shaped pragmatism and continue to structure today's debates about creativity. Key among them is the concern for overcoming the Cartesian split *between* the inside and the outside, mind and body, self and others, person and environment. These dichotomies resonate strongly within creativity research with its rather strict separation between individual or personal versus social or cultural forms of creative expression (Glăveanu, 2013). The pragmatist solution for escaping such harmful divisions was to focus on practical action and its development. Nevertheless, creativity scholars haven't fully integrated this insight and used it to transform the discipline.

The entry will start with an introduction of basic pragmatist premises and principles in philosophy and psychology, including ontological commitments, the focus on action and person–environment transactions, and the status of truth and knowledge. This account is necessarily selective given the historical richness of pragmatist and neo-pragmatist approaches and the exponential growth of the literature on creativity in recent decades. Then the focus will hone in on four main aspects of creativity research that have been impacted by and/or can benefit further from adopting pragmatist standpoints: creativity definitions and pluralism; action-based theories of the creative process; creativity development as a social process; and methodologies that embrace holistic needs. The ideas presented are derived from key pragmatist thinkers, who have made clear contributions about creativity, namely John Dewey, William James, Charles Sanders Peirce, and George Herbert Mead, as well as neo-pragmatists inspired by their original work. The conclusion calls for more pragmatist theories and research into creativity by pointing to their openness, participatory basis and emancipative power.

Pragmatist Propositions

Pragmatism may be portrayed as an anti-dualistic, action- and future-oriented philosophy that is concerned with the betterment of individual and collective affairs and aims to empower individuals to live a flourishing life. Besides solving real-life problems, shared ambitions of pragmatists are to shape future purposes, actions and experiences and to challenge limiting social and cultural structures and mechanisms in order to refine everyday conditions for practitioners. The pivot of these emancipative functions is human experience, which should be freed from mechanical routines, fixed habits, repetition, inequality, externally enforced labor, and practices based on dogmatic and traditional assumptions. In exchange, pragmatists cultivate inherently joyful and satisfactory experiences, activities that stimulate human powers, such as reflection, playful imagination, initiative, and open-mindedness. All these qualities enhance *growth*, that is, the constant reorganization of experience, by expanding perspectives and reconstructing new purposes and new ways to deal with the environment (Dewey, 1916). As pointed out by Joas (1996), John Dewey's main theme was “growth, self-enhancement, creativity” (p. 138). In Dewey (1916) own words, there are no (educational) ends beyond growth, since “life is development” and “developing, growing, is life” (p. 50).

From a pragmatist position – especially John Dewey's – the world can be understood as a practical and changing world, which we only become aware of through our actions and encountered obstacles. Hence, the world is not already there when we encounter it, but its peculiarities are brought to life by the transaction (e.g., when we confront problems). The social world is in a state of constant

flux – it is unstable, unpredictable and prospective. Hence, from Dewey's perspective, all individuals' embodied, subjective reality is constantly re-created by a *transactional* relationship between their personal capacities and environmental features (Biesta and Burbules, 2003). This transactional process is "active, adaptive, and adjustive", which means that its function is to maintain the balance between our inner and outer environments (Biesta and Burbules, 2003, p. 11), and that both situations and selves are continually reconstructed by this dynamic interplay (Elkjaer and Simpson, 2011). Personal capacities are affected by external features, while situational conditions are modified by internal dispositions. Therefore, all human conducts (e.g., creative actions), qualities (e.g., creative abilities), events (e.g., creative processes) and issues (e.g., creativity-limiting practices) should be grasped (and studied) as functions of the person-environment transaction. All persons are unique, and experience the world from different angles, by bringing different histories, desires and dispositions to the transaction (Biesta and Burbules, 2003). Hence, pragmatism implies that a person's socially embedded reality is emergent and changeable – an object is what (s)he experiences it as, at that given time and place. Who we are, how we perceive things and what we do in given situations depend on our past, present and projected relationships with the social, cultural, and physical environment. Considering this plastic worldview, there are multiple realities. This can both be a resource for the collaborative creative process (i.e., visiting each other's perspectives to get new ideas) and personally creative growth.

In the pragmatist tradition, truth is a subjective, mutable, situated and temporary feature that depends on the person-environment transaction. Pragmatists cannot talk of truth without referring to actual things, practices, or experiences. Like all other pragmatist topics, truth is interrelated with action. For example, William James argued that truth is not built into an idea, but *happens* to it, when applying it in practice: truth cannot be defined in advance, since the value or usefulness of ideas is realized by testing in a concrete situation (Rumens and Kelemen, 2016). In this regard, it could be argued that the truth of a concept, model or approach depends also on the creativity of its user. Basically, truth is "bound up with the way in which one moment in our experience may lead us toward other moments which it will be worthwhile to have been led to" (James quoted in Brinkmann and Tanggaard, 2010, p. 244). Therefore, some events are "truer" than others, and finding out which concept, belief or proposition is truest comes down to valuating and verifying its effectiveness in resolving a given problematic situation – how well it serves as a guide for action (Rumens and Kelemen, 2016).

Hence, pragmatic truth is interdependent with the process of *inquiry*, which regards:

controlled or directed transformation of an indeterminate situation into one that is so determinate in its constituent distinctions and relations as to convert the elements of the original situation into a unified whole

Dewey (1938, p. 108)

Resembling the creative process, inquiry involves sensing the need for change (e.g., being part of a situation marked by "unique doubtfulness", p. 109), conceiving the problem, observing the conditions, imagining and rationally crafting tentative solutions and the anticipated consequences of executing these corporeal operations, and then active experimental testing of their functionality in terms of efficiently resolving the disturbed situation (Dewey, 1938). Due to the transactional premise, all solutions are existential and temporal. We cannot be sure what happens when doing something (as the situation changes, the properties of truth also change), but only active and "experimental operations" (p. 121) – not reasoning alone – can modify the environmental conditions to re-establish transactional balance. Thus, Dewey (1938) understood truths, as *warranted assertions*, implying that (conceptual) outcomes of prior inquiries are carried on as virtuous, abstract inputs (or working hypotheses) to new inquiries, where they are tested by action or imagination, as potential "*means of attaining knowledge of something else*" (p. 122). Hence, pragmatism emphasizes the continuity of knowledge and action:

Only that [knowledge] which has been organized into our disposition so as to enable us to adapt the environment to our needs and to adapt our aims and desires to the situation in which we live is really knowledge

Dewey (1916, p. 344)

Hence, ideas, concepts, principles, etc., can only be accepted as knowledge when they are used purposefully to modify the environment. Knowledge is *used* in making sense of what is occurring in the moment and what should be done in the next one. Thus, knowledge is the *act* of applying dispositions to 'straightening out a perplexity, by perceiving the connection between ourselves and the world in which we live' (p. 344), an act that holds clear potential for creativity.

Engaging with the above premises, research does not generate new knowledge, but scientific ideas may become knowledge when applied in practice. Based on Dewey's *experimentalism*, which was his preferred name for his philosophy, theories should be treated as tools to play, think and create with in order to find prospective action possibilities, and facilitate learning, that is, "acquisition of more varied and complex predispositions to act" (Elkjaer and Simpson, 2011, p. 71). Accordingly, pragmatist studies should be evaluated based on their effectivity in inspiring and guiding the future practical affairs of communities, groups, or individuals.

For we live not in a settled and finished world, but in one which is going on, and where our main task is prospective, and where retrospect (...) is of value in the solidity, security, and fertility it affords our dealings with the future

Dewey (1916, p. 151)

Hence, endeavors in describing a world that has already passed only make sense when turned into a guide for future actions. As Dewey reminded us, the aforesaid emancipatory and utilitarian elements are central for the pragmatist conception of knowledge: Theoretical ideas should not only stimulate fresh moments in human experiences, but also have a moral character (Brinkmann and Tanggaard, 2010), that is, improve human conditions, events and purposes in a broader sense. Accordingly, pragmatists promote democratic ideals and values such as human growth, freedom, equality, diversity, tolerance, responsibility, and flourishing, as well as abilities such as problem-solving, critical thinking, communication and – as highlighted by the present entry – creativity.

Pragmatists tend to consider individuals as generative, autonomous agents, who are driven by a (creative) capacity and need for shaping and interfering with their physical and social environments. The possibility and tendency to do so depend on the transactional components, namely the quality of the social structures and generative capacities at play in the given situation (Rasmussen et al., 2017). From childhood, our activities are marked by an active exploration and redefinition of our situation (that is, creativity), but as life goes on, many people become inclined to adjust their actions to the environment (i.e., habituation) rather than modifying the environment to their own desires, interests and activities. For example, conforming traditions, dictating instructions, and the fixity of habits may neglect and impair creative qualities. As Dewey (1916) argued, people's original bodily *plasticity* – the natural ability to vary our actions until discovering an efficient and appropriate solution – is forsaken by environments that are not ensuring 'the full use of intelligence in the process of forming habits' (p. 49), meaning that they cannot engage in undertakings requiring conscious deliberation, reflection, decisions, and creative actions.

Demonstrating how these ontological and epistemological commitments of pragmatism underpin and inform the research process, the following sections deal with four key issues within creativity research: 1) definition, 2) nature, 3) development, and 4) measurement.

Creativity Definitions

Committing to the transactional premise and the idea that we as unique individuals operate experimentally in a social, unstable and changeable world, pragmatism is marked by welcoming *pluralism*, meaning that pragmatists celebrate and encourage a multiplicity of "values, experiences, meanings, perspectives, and methodologies" (Rumens and Kelemen, 2016, p. 12). In William James' view, the world is full of indeterminate possibilities. There are numerous ways of engaging with, expressing in, describing, interpreting, and transforming the world.

Serving the present purpose, pragmatism offers a "pluralism of knowledge" by recognizing the validity of a variety of individual and collective interests, perspectives and forms of knowledge (Cornish and Gillespie, 2009). Pragmatism also fosters what can be called a "pluralism of experience". For James, *experience* continually envelops external objects, their relation to each other and to our purposes, which enable us to handle and shape the environment in meaningful ways (Rumens and Kelemen, 2016). This continuity enables us to use past experiences and present perceptions as instruments to anticipate and handle future experiences. Such a future-oriented process allows us to act in new ways and to evaluate the effectiveness of these acts. Similarly, for Dewey, experience regards the continuous and dynamic partaking in, and transactional adjustments to, the physical and cultural environment. When we experience something, we are acting on things; we are doing something and are undergoing the consequences of these doings (Dewey, 1916).

Reflecting the notion of truth, pluralism does not mean that all concepts, beliefs or definitions are equally beneficial – some ways of engaging with the world are better than others. Although acknowledging diverse, competing forms of knowledge, pragmatists would explore and conceive

- a) origins of opinions;
- b) interplay between beliefs, context, and history;
- c) sensible actions a definition gives rise to;
- d) potential practical consequences of applying particular approaches.

Further, pragmatists question whose and which interests are addressed, disregarded or undermined (Cornish and Gillespie, 2009) in the given situation. As outlined above, such queries pursue a democratic ethics to avoid adherence to authorities, customs, and impulses. For Dewey, democratic communities should improve the life for everyone, rather than for the selected few.

Pragmatic pluralism was central to our recent study in a Danish soccer talent development environment (Rasmussen et al., 2019) where qualitatively different conceptions of creativity were explored. Interviews with coaches and observations of training activities formed the experiential underpinning that led to a conceptual landscape covering 15 metaphors (e.g., *transgression*, *magic*, *invention*, *surgicity* and *choreography*), embodying a diversity of meanings, values, and applications of creativity. Although embracing these fluid and plural ways to approach creativity, the metaphors were contrasted in terms of their appropriateness in serving all players. Among others, this showed that coaches disagree which players (and positions) are creative, why creativity is important and how it is nurtured (each coach applied a unique selection of metaphors). For example, some supposed that pre- and post-game creativities (e.g., *exploration*) were vital to develop as a player and enjoy the game (i.e., aiding everyone); others believed that in-game creativities (i.e., *deception*) enhanced the likelihood of being victorious (i.e., spotlighting offensive players). Also, application of growth-related variants stressed originality (e.g., letting players decide; try novelties), but the game-decisive ones accentuated appropriateness (e.g., equipping players with useful tools; do the most effective). This study may expand, in a pragmatist manner, the experiences of actors in sports, and entail more nuanced dialogues about sporting creativity. Given our uniqueness, everyone can pass distinctive things to others, if able to turn experiences into ideas (Joas, 1996).

Pragmatist pluralism entails that there are many ways to conceptualize the world and its parts. No matter whether they are “humble guesses or dignified theories” (p. 160), definitions do not offer factual ways to conceive the world (Dewey, 1916). Offering varied accounts of or perspectives on the world; definitions are “forecasts calculated to influence responses” (p. 178). By means of dialogue and experience, a single approach may be recognized as superior in achieving particular ends, but there is no unconditional “best” approach (Cornish and Gillespie, 2009; Rumens and Kelemen, 2016). Finally, pragmatism encourages students and researchers to accept one’s shortcomings, be open to otherness, and avoid fixity of doing or thinking (e.g., preferred definitions). Hence, when examining rival positions or assumptions, pragmatists should aim to seek common ground, understand the differences, and grasp the other positions in the strongest way possible.

The Nature of Creativity

Pragmatist scholarship has a unique contribution to make to our understanding of the nature of creativity itself. This is the case given that pragmatists have been keen to engage with a dichotomy that is central for the very setup of creativity studies – the dichotomy between “inside” and “outside” of the creative person. Since early on, the scientific study of creativity has focused on intra-psychological correlates of creative expression. For example, J. P. Guilford, in his celebrated address to the American Psychological Association, encouraged fellow psychologists to research and to educate what he called the “creative personality.” In the decades that followed, researchers explored in-depth the “inner” attributes of creators including intelligence, motivation, thinking styles and thinking processes. Meanwhile, since the 1980s, a sustained critique of this focus on isolated individuals emerged in the form of Csikszentmihalyi’s systemic and Glăveanu’s distributed models. The latter are particularly inspired by pragmatist ideas in that they don’t call for a focus on elements “outside” the creative individual but aim to do away with the inside–outside dichotomy altogether. In other words, they advocate for the study of *creative action* (doing or making) not as opposed to but as integrating creative thinking.

This ethos to transcend the Cartesian split between person and environment has been foundational for pragmatists. In 1896, John Dewey wrote a seminal paper criticizing the traditional conception of the *reflex arc* in the psychology of the time. In particular, he questioned the artificial separation, in the reflex arc, between stimulus (external) and perception (internal), as well as that between the sensorial (cognitive) and the motor or response system (bodily). Instead of a disjointed mechanism, Dewey proposed the notion of *coordination* in order to bring together the sensory stimulus, the central processing, and the motor discharge. Instead of artificial separations, he proposed a holistic and dynamic perspective on the whole process of “sensation-followed-by-idea-followed-by-movement” (Dewey, 1896, p. 358). These *action-perception loops*, as they would be later interpreted by cognitive science, are crucial not only for functions as basic as perception, but also for phenomena as complex as creativity. In fact, Dewey went on to propose a similar view of interdependence and coordination between action and perception within the creative act in his seminal work *Art as Experience* (1934). He described the process as follows:

Antecedent subject-matter is not instantaneously changed into the matter of a work of art in the mind of an artist. It is a developing process. As we have already seen, the artist finds where he is going because of what he has previously done; that is, the original excitation and stir of some contact with the world undergo successive transformation. The state of the matter he has arrived at sets up demands to be fulfilled and it institutes a framework that limits further operations (p. 116).

For Dewey, therefore, artistic creativity is best described as a developing form of acting or, better said, inter-acting in and with the world. This action is made up of a cyclical relation between *doing and undergoing* or acting on the environment and being acted upon, in return, by the effects of one’s doing. This basic process that, for Dewey, characterizes human experience, can be applied beyond art to many other domains of creative production. In fact, as we argue here, it captures something essential about the nature of creativity when theorized in terms of action: the fact that it bridges the external and the internal, self and others, person and context. Creative thinking, just like the sensation within the reflex arc, is not a separate component of creativity – it “extends” into the world through the creator’s doing and it is enriched by its undergoing (similar to Piaget’s notions of assimilation and accommodation).

But isn’t the cycle of doing and undergoing broader than even creativity? Doesn’t it capture something essential about human action – and human life – in general? Joas and Kilpinen (2006), building on pragmatist accounts, believe so and, because of this, made the strong claim that “creativity constitutes human action in its entirety” (p. 323). For them, we should not be talking about creative individuals or creative products, the only entity that can have this attribute is human activity. And, for the most part, this activity is *necessarily creative*, to a smaller or greater extent. This is due to the fact that there is no separation, again, to be upheld between thought and action: we think with and through the means of action and we act in ways that are both guided by and guide our thinking. The potential for novelty, improvisation, and emergence is thus ever-present. In this way, from a pragmatist standpoint, a study of the nature of creativity leads us to a deeper understanding of what makes us human and not vice versa.

The Development of Creativity

If creativity is intimately related to human nature, then their “origins” should also be similar. And, indeed, a pragmatist study of the emergence of a *human self* reveals a new facet of their deep interconnection. In order to grasp it, we need to turn to the work of

another well-known pragmatist, George Herbert Mead. The central question in Mead's philosophy and social psychology is related to the construction of the self. His answer to this question points us to the birth of *reflexivity*.

The self emerges at the moment in which it becomes capable to *take the perspective* (role or attitude, in Mead's initial terminology) of the other upon the self. This process requires both a form of decentration from one's own position and perspective in the world and a bridge toward the subjectivity of another person, understood as similar to one's own. The first implication of this view is that the mind and the self are a "not initially there at birth, but arise in the process of social experience and activity" (Mead, 1934, p. 255). Second, this dynamic has deep consequences of human *agency* and, by extension, for creativity. The social act of taking the perspective of another upon oneself not only marks authentic forms of intersubjectivity, but also makes the self's relation to the world – including oneself – more flexible. By becoming capable to understand the world and act within it (for the connection between thinking and action revisit the previous section) from a different position, the person expands his or her own horizon of *possibility*. Instead of being "trapped" within singular and egocentric perspectives (which tend to dominate in the case of animals and new-borns), a social self can entertain multiple perspectives and, in doing so, reflect and become agentic in relation to them. In the end, the same space of multiple perspectives and reflective dialogues between them is at the heart of creativity (see the perspectival model; Glăveanu, 2015). From a pragmatist standpoint we can argue, thus, that creativity and the self are twin-born, developmentally, in the act of perspective taking.

This last idea has been developed by Gillespie and Martin, two neo-Meadean scholars, into what they call Position Exchange Theory (PET):

The first assumption is that society comprises a multitude of social positions, many of which are interdependent (Durkheim, 1893). Social positions only exist in social situations. They are socio-institutional locations within our social structure from which people speak and act, constituted by rights, responsibilities, and situational demands. (...) The second assumption is that social positions constitute perspectives, that is, psychological and embodied orientations, interests, and even world views. (...) The third assumption is that people move between social positions

Gillespie and Martin (2014, p. 74)

Taken together, these assumptions are highly illuminating for the development of creativity. It is because we get to occupy different positions in the world, initially through pretend play, that we get, in an imaginative and embodied manner, to experience the world from their different perspectives. The possibility of moving between positions, which is at the basis of social interaction, facilitates exchanging perspective and, in the process, integrating and multiplying them. The latter are creative processes or, at the very least, processes that hold promise for creativity. In this manner, pragmatically, creativity emerges out of self-building acts such as *position exchange and perspective taking* and, in turn, becomes the dominant characteristic of the newly created self. Decentering from one's own position and perspective are not only crucial developmental achievements for the person according to Piaget, but also an essential condition for creative expression. As such, creating comes to bridge not only the internal and the external, as mentioned before, but also the dichotomy between self and other. If theoretically this degree of complexity can be easily explained using a pragmatist vocabulary, it is intrinsically difficult to study creativity in the same holistic and dynamic manner at an empirical level. This leads us to a last challenge: the methodological one.

Creativity and Methodology

As a non-foundationalist position, pragmatism rejects fixed, objective methodological criteria. No single design, method, or theory is intrinsically best for pragmatists, but some are more useful in serving particular research purposes and interests. Still, the pragmatist principles may guide which kinds of questions are asked and how they can be answered. Reminiscent to the standard definition of creativity, pragmatism urges scholars to generate original and useful (as well as more complex) ideas, purposes, processes and ends – for people, scholars and societies.

Evocative of the spontaneous and inventive search for potential solutions during inquiry is C. S. Peirce's notion of *abduction*, which may be described as an extending and speculating approach to inquiry, where explanatory propositions, hunches and ideas are produced and explored. As the only way to form new hypotheses, Peirce believed that abduction was "a necessary, but not sufficient, condition for the advance of science" (Joas, 1996, p. 134). Contrary to the constrained and retrospective processes of induction and deduction, imagination prevails in abduction to create novel purposes and solutions and anticipate their consequences, project alternative futures, and open ways to engage with the environment that were previously tied by historical bonds (Elkjaer and Simpson, 2011).

Based on the transactional premise, pragmatists approach social practices as complex, temporal interweaving's of social agency and social situations (Elkjaer and Simpson, 2011). Since practices are inseparable from the continuity of experience, its meanings and actions are constantly moving. Engulfed by adaptations across persons and environments, Dewey (1938) suggested that scholars interested in the social world should do experimental research on human reactions, what we are influenced by, and how we change, that is, studies "on the process and from within the process" (p. 180). This calls to participative, action-oriented research, and turn attention toward temporal aspects.

As implied in "The Nature of Creativity" section, pragmatists do not understand inner and outer processes, or personal and environmental features, as discrete entities, but as mutable, inter-reliant constituents of an integrated whole. Pragmatism emphasizes

holistic, contextualized, and problem-focused approaches that address intertwined, immanent features and dynamic processes (Elkjaer and Simpson, 2011). These premises permeated our aforesaid study in the context of soccer (Rasmussen et al., under review), where the creativity conceptions were grasped as fluctuating and fragmented, cultural discourses, continuously growing out of and informing coaching practice. Forming a multifaceted, interactive, organic and flexible typology, this ecosystem of beliefs exhibits the unique complexity of creativities fostered in the specific context at that time of our study. Lacking a shared approach to creativity, the coaches made sense of the term in relation to personal experiences and soccer philosophies, local tactical principles, and general tendencies in the world of soccer. They utilized, appropriated and transformed diverse perspectives to serve heterogeneous purposes and interests. Although these findings are context-dependent, located in and bound to the transactional process of the specific inquiry, they add pragmatic value by disclosing local presumptions, routines and discrepancies regarding creativity and its promotion on the one hand, and a plurality of ideas regarding creative qualities and creative training activities on the other.

Extending the pragmatist interest in studying “what works”, how and why it does or doesn’t work (Rumens and Kelemen, 2016), Brinkmann and Tanggaard pointed out that the most exciting question for pragmatists is which kinds of actions and experiences are facilitated by a particular principle or approach. Surpassing traditional philosophies that draw attention to actors, pragmatism focuses on studying situated human actions, including both doings and sayings (what and in which way things are said or done) as well as and effective and failed actions, to grasp how individuals and groups make sense of their world. It is particularly interesting to explore how actors experience the world as meaningful in contexts where the environing conditions are (or have been) reshaped to develop creativity, e.g., by tracing actions and experiences throughout the process of re-organization. This may lead to discovering and formulating relations between personal and social qualities that facilitate creative actions and/or enhance our creative powers.

Conclusion

What can pragmatism teach us about creativity? First, that creativity is a problem of life: we all do and experience creativity in various guises and are subjected to numerous situations where we are required to act creatively. Second, that creative phenomena are plural and multifaceted, and they are both defined and expressed within everyday contexts of living. Third, that their expression is rooted in action and interaction, engaging both self and other in an act of co-constructive participation.

The pragmatist idea about the constitutive *power of knowledge* in terms of defining our possibilities and problems, and favoring of inquiry and experience as pathways to new knowledge carry a huge potential for creativity scholars desiring to develop emancipatory, anti-oppressive, as well as culture critical and inspiring research (Cornish and Gillespie, 2009). Pragmatists values scholarships that challenge assumptions and create richer futures, by offering new ways to think and act, or guiding social reform, that is, modification of environing and existential conditions so people are enabled to thrive, living their common life in a gratifying and fertile way.

Reminding ourselves of the widespread potentials of creativity in terms of enjoyment, learning, adaptation and societal progress, pragmatism offers a sound basis for doing various kinds of *creativity-developing research*. The most important legacies of the pragmatist philosophical tradition in terms of doing creativity research are to expose, enlighten and subvert creativity-limiting practices and to cultivate democratic communities of creative and critical inquirers, who are able (and free) to utilize their creative potential and handle everyday problems as they arise. On this account, the *emancipatory element* of pragmatism regards developing creativity-nurturing communities and enabling people to acquire the knowledge required to gain creative control of their own life.

Pragmatism not only have a special contribution to make to the understanding and practice of creativity, but also suggests that these should be revisited by the community of researchers for new insights into what it means to create not as isolated brains or minds, but as full human beings living in a shared socio-cultural and material world.

What Is Problem Finding?

One major approach to the study of creativity is the examination of cognitive processes involved in creative problem solving and creative thinking. Most of the cognitive process models include problem finding or an associated construct as the first step (e.g., Dewey, 1910; Guilford, 1967; Mumford et al., 1991; Newell and Simon, 1972; Sternberg, 1986). J.P. Guilford was the first to recognize the importance of problem finding, coining the term “sensitivity to problems”. Other models have used terms such as problem definition, problem identification, problem formulation, problem generation, problem discovery, and problem construction. While specific definitions of each term vary somewhat, all have a common thread and to prevent confusion, the term problem finding will be used throughout this entry. Problem finding is viewed as an umbrella term and includes the multiple aspects delineated in the literature. Reiter-Palmon and Robinson (2009) indicated that problem finding includes multiple aspects. One includes problem anticipation and identifying problems or opportunities in the environment when they are not presented to the problem solver. The second aspect includes structuring and defining the problem in a way that provides a starting point to formulate a solution.

Other research differentiated problem finding tasks by the degree to which the problem is given to the problem solver (e.g., Reiter-Palmon and Hullsiek, 2010). This ranges from problems that are well structured and given to the problem solver (presented problems), to ill-defined problems where the problem solver identifies the problem (discovered problem), to problems that have yet to be explicitly recognized and are found or generated by the problem solver (created or generated problem). The role of problem finding is particularly important when problems are ill-defined for two reasons. One aspect of problem finding calls for identifying possible problems in the environment, many times when problems are not clearly identified, or even known. These types of problems are ill-defined by definition, as no problem is presented to the problem solver. The second aspect requires the structuring and defining of the problem. If the problem is well-defined or structured, there is no need for problem finding.

It is important to note that while problem finding is seen as the first step in creative problem solving, followed by other processes such as information search, idea generation, and idea evaluation, the creative problem solving process is not as fixed. Creative problem solving can be interpreted as more cyclical in nature. Likely as a result of difficulties encountered in later processes individuals may cycle back to earlier processes. For example, finding new information that requires the individual to think about the situation or problem in a new way may result in reformulation of the problem. Similarly, if during idea evaluation, the individual identifies that no good ideas were developed, he or she may cycle back to earlier stages – either to the idea generation phase or the problem finding phase.

The Process of Problem Finding

While most creative problem solving models include problem finding as the first process, there only a limited number of models of the problem finding process itself. Early models such as those by Dewey (1910) and Guilford (1967) provided a separation between problem recognition followed by problem definition. Basadur (1995) has suggested that both ideation and evaluation play a role in problem finding.

A more detailed process model of problem finding has been suggested by Michael Mumford et al. (1994). This model starts with attention and perception. Individuals need to attend to and perceive a gap or a problem in the environment. It seems that when

[☆] *Change History:* August 2019. Roni Reiter-Palmon updated some sections.

This article is an update of R. Reiter-Palmon, Problem Finding, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 250–253.

problems are well-defined, there is no such perception, and the process of problem finding either is bypassed or occurs quickly and automatically. This first step corresponds to what appears in theoretical models as one aspect of problem finding – problem anticipation or identifying opportunities in the environment. Attention and perception of environmental cues trigger problem representations. Problem representations are knowledge structures based on past problem solving efforts and include four types of information (a) the goals and outcomes associated with the problem solving effort, (b) information required to define and solve the problem, (c) procedures and operations performed on the information in order to solve the problem, and (d) constraints and restrictions on the problem solving effort.

Problem representations are activated through environmental cues. If the problem representation has been associated with a specific cue in the past, it will be activated. More ill-defined problems and situations are likely to have more diverse and complex set of cues. In addition, ill-defined problems will likely have cues that are associated with multiple problem representations resulting in more problem representations being activated. As the problem or situation is more well-defined, structured and less complex, it is more likely that a small number, or even one, problem representation will be activated. If the problem is identical or very similar to a problem solved in the past, the problem representation associated with that problem solving effort will be activated. When only one problem representation is activated, it is likely that the problem solver quickly and automatically completes the problem finding process moving immediately to problem solving. When multiple problem representations are activated, and a single problem representation cannot be used, the problem solver must find a way to create a new problem representation that includes a mix of the elements from the activated problem representations to guide problem solving. This will likely result in a more creative way to define the problem, and therefore more creative solution.

The process described above has several important implications. First, in most situations, problem finding will occur automatically. These situations include routine problems, problems that have been encountered before and solved successfully, or problems that are similar to previously encountered problems. Active engagement in problem finding will occur only when the problem is different enough from past experiences or includes diverse information that elicits multiple problem representations. A second implication is that the problem finding process, like the creative problem solving process as a whole, includes both divergent and convergent elements. The activation of multiple problem representations, multiple ways of perceiving the problem, is a divergent process. However, the integration of the various problem representations into a new single coherent (and original) representation is a convergent process. Finally, an important implication of this model is the role that knowledge plays in the problem finding process. Activation of problem representations occurs based on the similarity of cues perceived in the environment and existing problem representations. Therefore, some knowledge is necessary for effective problem finding to take place. Further, the availability of a pool of potentially useful problem representations would be beneficial.

Importance of Problem Finding

Problem finding has been linked to creativity in a wide range of domains. The seminal study by [Getzels and Csikszentmihalyi \(1975\)](#) linked problem finding behaviors with originality and aesthetic value of paintings created by art students. More importantly, problem finding measures were also predictive of success as an artist measured 7 and 18 years later. Problem finding has also been found to predict creative accomplishments and creative problem solving in everyday problems. In addition, problem finding has been found to predict creativity above and beyond known predictors such as divergent thinking and intelligence. Research suggests that problem finding seems to be characteristic of creative individuals.

In addition, problem finding has been found to be related to creativity overall. Laboratory studies in which problem finding has been manipulated find that individuals that engage in problem finding are more likely to generate creative ideas compared to those that do not. In addition, research has shown that the quality and originality of problem restatements predict solution creativity ([Arreola and Reiter-Palmon, 2016](#)).

Factors Affecting Problem Finding

Research finds that problem finding is indeed an important process in the creative problem solving process and can influence later processes. However, it is also important to understand the factors that influence effective problem finding and therefore may have an effect on creativity. One of the most accepted finding has been that active engagement in problem finding results in increased creativity. Multiple studies, employing various methods to induce active engagement have found that active engagement in problem finding increases the creativity of the process itself and of the resulting solution. In some studies, participants were given instructions to think about the problem prior to solving it, to identify goals, or to rephrase the problem in different. Other research has induced active engagement by training the problem finding process (alone or in combination with other creativity relevant processes). Research evaluating training programs designed to improve the problem finding process finds not only improvement in this process, but also in creative problem solving in general. In addition, a meta-analysis on the effect of creativity training has found that training in problem finding resulted in improved creativity across multiple studies, and was one of the best interventions for improving creativity.

Individual differences also play a role in the problem finding process. First, several studies have found that problem finding ability was related to more original problem finding and increased creativity of the solution. Additionally, individuals who are more creative as well as experts spend more time defining the problem. The effect of expertise on problem finding however, is

not fully understood. Experts spend more time defining the problem relative to novices, and are likely to have more problem representations that can be used in defining the problem. Conversely, experts are more likely to evaluate new problems as similar to those that they have encountered in the past, resulting in the use of a dominant problem representation. On the other hand, it is possible that experts find particularly creative solutions to problems by actively identifying constraints.

In addition to problem finding ability and expertise, recent work has suggested that dialectical thinking, the ability to work with and accept contradictions is related to problem finding. Other personality variables linked to problem finding have been those that traditionally have been related to creativity in general. Variables such as openness, tolerance for ambiguity, and flexibility have all been found to be related to creative problem finding. It is not surprising that the variables that emerged as related to effective problem finding tend to be those that related to cognitive style or individual difference in processing information.

Other types of individual differences variable related to problem finding are related to motivation. Individuals who see themselves as creative, have creative self-efficacy, and self-esteem, tend to also be more likely to engage in effective problem finding. Active engagement in problem finding is an effortful and time consuming activity. It is therefore likely that only those individuals who are motivated to engage in the process will do so. While some research exists on the role of personality and motivational variables in problem finding, the literature is limited, and more work is needed.

Situational variables also exert an influence on problem finding. The type of problem or task is one variable that has been investigated. More ill-defined problems allow for more problem finding. Further, more solutions are generated to problems that are created or generated by the problem solver as opposed to a presented problem (even when it is ill-defined) When problems are generated, they may reflect the interests and concerns of the problem solver and therefore are more likely to be more involving and interesting to the problem solver, which would speak to the motivational aspects of problem finding and creativity.

Other task characteristics include the degree of consistency of information presented in the problem. More ill-defined problems tend to include more diverse cues, some of which may be inconsistent or in conflict with one another. Diverse cues or contradictory information in the problem has been linked to increased originality and creativity of the solutions, presumably based on the effect these cues and contradictions have on the diversity of the problem representations activated and the need to integrate diverse problem representations. This finding mirrors findings regarding individual differences, where dialectical thinking, has been linked to increased problem finding and creativity.

Task effects and domain effects have emerged as an area that influence various findings regarding creativity. A recent meta-analysis suggests that the relationship between problem finding and creativity is dependent on domain and measure of creativity (Abdulla et al., 2018). Specifically, problem finding was found to be a stronger predictor of creative products than divergent thinking. In addition, problem finding was found to have a stronger relationship with creativity as measured by fluency and originality for divergent thinking compared to other measures.

Finally, available time and time pressure will likely affect the problem finding process. Problem finding takes time and effort, and past research has consistently found that individuals who spend more time on this process, develop more alternatives for how the problem is viewed, and also develop more creative ideas. Because the process tends to be automatic most of the time, it is likely that time pressure will result in an automatic application of the process instead of active engagement.

Measurement of Problem Finding

One of the more difficult issues when studying problem finding is the measurement of the process. As problem finding is typically automatic, and does not have an outcome that can be evaluated, probing is necessary to observe the outcome of the problem finding process. A typical approach of evaluating problem finding involves asking participants to define the problem in multiple different ways. However, this probing is a direct manipulation of problem finding, one that is also used to induce active engagement in problem finding. It is therefore difficult, if not impossible, to study problem finding directly without also manipulating it. In order to further our understanding of the problem finding process, it would be helpful to identify a way to measure problem finding without manipulating it or creating active engagement. This will allow the study of problem finding in its natural form.

The fact that measuring problem finding requires the manipulation of problem finding also raises another important issue. How problem finding is manipulated may affect the results of the process. One popular method uses a variation of Baer's (1988) approach, in which an ill-defined problem is presented, and participants are asked to restate the problem in as many different ways as possible. This sort of manipulation induces active engagement and forces participants to think in an effortful manner about how to define the problem. In addition, this specific approach seems to be geared toward a focus on goals, which are only one element of the problem representation. It is possible that different approaches for inducing active problem finding, with a focus on other elements, such as constraints or information needed, may result in somewhat different outcomes.

Finally, the approach discussed above for eliciting information about the problem finding process presents the problem solver with an ill-defined problem. Providing the problem to be solved allows for control in the study of problem finding, as all problem solvers react to the same stimulus. However, by providing all problem solvers a problem, the focus is on one aspect of the problem finding process, that of structuring the problem. As stated, problem finding includes both the process of identifying opportunities and problems as well as defining what the problem is. When the same ill-defined problem is presented to all participants, by definition, researchers are focusing on presented problems and the process of defining the problem. Generated problems and the process of identifying problems and opportunities cannot be investigated when the same ill-defined problem is presented. Only

a handful of studies have evaluated the latter, finding increased creativity for generated problems compared to presented problems (e.g., Runco and Okuda, 1988).

Teams and Problem Finding

Teams are faced with many opportunities to engage in problem solving, including creative problem solving. Organizations use teams to address the need for having multiple stakeholders (such as members of different departments) involved in decision making, or when problems are too complex for one individual to solve. Research on cognitive processes at the team level, whether they relate to creativity or more routine problem solving efforts, is sparse. The only area that has received much attention is that of brainstorming. However, both earlier processes to idea generation such problem finding, and later processes such as idea evaluation have received some attention. Extant research on problem solving and teams suggest that teams engage in cycles of experimentation. These cycles involve sequences of activities performed by the group that lead to insights on requirements and constraints. This process resembles the problem construction process found when individuals solve creative problems.

When individuals work in a team to solve problems, problem finding must be evaluated from two perspectives. Each individual within the team will engage in problem finding and the problem may be defined differently by each individual. Problem finding and defining of the problem is a result of the problem representations elicited by the cues in the environment. Both attention to these cues as well as the problem representations available to the individual will be based on past experiences. Since past experience will differ from one person to another, it is reasonable to expect that when problems are ill-defined, individuals within a team will view the problems in different ways. Past research on team problem solving and decision making suggests that teams that are homogeneous (based on gender, expertise, and the like) are more likely to experience difficulty reaching a consensus on a solution and difficulty communicating effectively.

The availability of multiple problem representations at the team level, just like at the individual level, may lead to integration of these problem representations in new and creative ways, leading to a new problem representation and more creative solutions. However, as individuals typically engage in the problem finding process automatically, further, they may not be aware that other members of the team may define the problem in a different way. This may lead to misunderstanding and difficulty in communication that can be found in heterogeneous teams. Further, it is less likely that individuals will discuss the problem finding process or how each person defines the problem. Teams typically focus on the solution that is needed, and team members assume that other team members view the problem in a similar fashion. Disagreements about solutions may often be traced back to lack of agreement on how the problem is defined or the elements of the problem, such as differences in goals, restrictions, or information available or needed. Presumably, a collective problem construction process alleviates tensions and disagreements that may arise from the differing representations. Teams that engage in problem construction have been found to produce more original ideas than teams that do not engage in the process. Moreover, team problem construction facilitates social processes in addition to team creativity. Groups that construct and find problems together experience less conflict and report higher levels of satisfactions than groups that do not engage in a problem construction process.

On a larger, organizational scale, differences in problem representation also appear to affect how organizational groups construct problems. The dissimilarity of representations between groups stems from differing frames of interpretation. Often, collections of groups within an organization may hold distinct perspectives from each other. Research has shown that departments within a company draw from differing frames to solve problems related common organizational goals. As a result, these groups construct these problems differently. Furthermore, departments within an organization are often unaware that they have unique approaches to achieving common goals. Paralleling what occurs in team problem solving, disagreements and misunderstandings arise between departments. Further research is needed to determine whether a shared problem construction process would produce benefits at the organizational level.

While the last decade has seen an increase in empirical work on this topic and more is known today about problem finding, there are still many unknowns. Empirical research is needed in areas of the different types of problems and problem finding (such as problem identification vs. problem definition), measurement of problem finding, individual differences and situational variables that influence problem finding, and the process of problem finding in teams.

Definition of Prodigy and Conceptual Distinctions

Stories about children with extraordinary performance levels have always captivated the scientific and the public interest. Children who show high-level performance in highly demanding fields before the end of primary school (or before the age of 10) are known as prodigies. Some of the most known examples of prodigy children come from the domain of music. Mozart, Chopin, and Liszt exhibited remarkable musical performance skills from very young ages. There are also examples of children with exceptional performances in mathematics and chess. In domains such as the visual arts, science or literature, remarkable achievements are found only in older ages. Albert Einstein or Charles Darwin are known as geniuses rather than prodigies because science is much more complex and requires a longer period to develop the expertise that is required for notable achievement.

“Prodigy” has overlapping characteristics with other phenomena such as talent, giftedness, and expertise. Ellen Winner, who has written extensively about talent, giftedness and prodigy, conceives of these concepts on a continuum with no strict delimitation between them. Nevertheless, these terms are often used interchangeably in a misleading way. It is important to notice that the term prodigy designates a child that is both talented and gifted, and who demonstrates expertise in a specific field. However, a talented or gifted child is not necessarily a prodigy. Nor is child prodigy a prerequisite to obtaining adult expertise.

There are far more studies on giftedness than on prodigy, most likely due to the fact that prodigies constitute a very small sample of the population and they are very young.

In order to better differentiate among the concepts provided above, one should keep in mind that: 1. A prodigy is a young child (usually below the age of 10) who exhibits expertise at the level of performance in a given domain; 2. A gifted person, both child and adult, has the potential to have superior performance but does not necessarily achieve it (as prodigy children do); 3. An expert has high performance in a domain, which can be achieved by practice alone.

The chapter continues with current explanations of the prodigy phenomenon, and then with the analysis of its relationship with creativity. We will end with some open questions that are likely to spur further research in this fascinating area.

Going Beyond Descriptive Explanations of Prodigy and Heading Towards Mechanisms

Most of what we know about prodigy comes from descriptive and observational reports, focused mainly on identifying the characteristics and traits of prodigies. Currently, there is no explanatory model of the phenomenon. Some of the outstanding questions to answer are: What are the mechanisms behind their accelerated learning? To what extent is the strong motivation of prodigies a learned characteristic or a biological predisposition? Below we will address the core ideas for some of the most important approaches to the study of prodigy: developmental psychology, genetics, expertise research and neurobiology.

Developmental Explanations

Some authors argue that child prodigy is a result of a very accelerated development. In her cognitive-developmental theory, Shavinina (2010) argued that the underlying mechanism of the prodigy phenomenon consists in the sensitive periods and unique cognitive experiences that prodigies develop. In other words, child prodigies have a special age sensitivity that represents a “very selective responsiveness ... to everything what is going on around him or her” (Shavinina, 2010, p.33). Shavinina differentiates between cognitive sensitivity (i.e., to new information), emotional sensitivity (i.e., to the inner world), and social sensitivity (i.e., intersection with one another). In her approach, sensitive periods are the age periods in which the child has heightened

sensitivity. In case of prodigy children, the sensitive periods unfold very early (i.e., some prodigy children can learn the alphabet as soon as two years of age) and they overlap, which gives them the power for intellectual growth in a very short period of time. Due to this overlapping, prodigies seem to be almost always in sensitive periods (Shavinina, 2010). Because sensitive periods are present in any individual's development (typical or atypical) (Schaffer, 2004), it is unlikely that the sensitive period per se, but rather the overlapping of many sensitive periods, could represent a mechanism. This idea needs empirical proofs before one can assert the presence of this kind of mechanism.

There is some indirect evidence that sensitive periods play a role in this phenomenon. Brant et al. (2013) showed that adolescents with high IQ experience longer sensitive periods and longer influence from the environment compared to adolescents with lower IQ. The study suggests no direct causality, but leaving aside the debate over considering IQ or not as a sign of giftedness, it does lend support to the idea that different kinds of sensitive periods (longer or overlapping) are a characteristic of exceptional development.

Similarly, from a developmental perspective, Simonton (1999) presents the emergenic and epigenetic model of talent development. This model suggests that an endowed capacity has multiple components which must each be inherited for the capacity to be present (i.e., emergence), and it emerges gradually during interactions between the organism and environmental stimulation (i.e., epigenetic). From this point of view, prodigies get it all together early (Simonton, 1999, p. 443). But this early manifestation is also allowed by certain domains more than by others, namely those with fewer components needed (like music, mathematics, and chess, Simonton, 1999). As such the endowed capacity is always interacting with the environment and it does so in a multiplicative manner, so that over the course of development the child becomes able to perform in unimagined ways.

Is the prodigy phenomenon domain-general or domain-specific? There is research that argues for domain specificity, especially for cognitive profiles that differ by domain. Ruthsatz et al. (2014) showed that while average or high IQ, exceptional working memory, and very good attention to details are all needed, the scores on these cognitive underpinnings differ in domains like art, music, and math. Children with math precocity had the highest IQ, music prodigies had the highest working memory scores; counterintuitively, art prodigies have low visual spatial skills that are explained tentatively via a different type of perceptual skills in talented artists, namely a very good attentional focus on details. These results speak for the idea of specific developmental trajectories that might be important to investigate if we want to fully understand the prodigy phenomenon. In other words, exceptionally early high performance in different domains might be sustained by slightly different abilities; as a consequence, we might need to analyze more thoroughly these differences.

New research suggests a link with autistic traits but also some differences when compared with autistic children. Ruthsatz and Urbach (2012) found that child prodigies have high scores for attention to detail (even higher than the group with Asperger's syndrome) but they do not have other traits associated with autism. Prodigies also had many relatives with autism. The authors ask: What moderates the lack of autistic deficits in child prodigies? And they suggest looking for a biological modifier that acts like a moderator for autism (Ruthsatz and Urbach, 2012).

Studying prodigies is made difficult by the fact that we usually acknowledge their existence after they have proved their performance; as such, it is difficult to investigate the prerequisites that are needed for becoming a prodigy. A true developmental approach would point to the mechanisms that lead to the performance of prodigies; otherwise we cannot escape the circularity of causation. This approach is still awaited for.

Genetic Versus Environmental Explanations

High achievements, which are central elements of prodigy, have been debated for a long time through the dichotomy of innate versus environmental basis. From one side, the nurture view suggests that prodigies are the result of environmental factors and an intense deliberate practice and effort. Essentially, it is suggested that enough practice and hard work is all that is needed to reach extraordinary achievements in any domain. This view is supported mainly by studies on eminent people in science, arts, and athletics whose expertise is thought to be achieved through a supportive and encouraging environment from their parents and teachers, including a long and intensive period of training. The role of environment has also been supported in studies on adult experts in piano, violin, chess, bridge, and athletics where it was found that the levels of achievement reached in these domains correlate strongly with the amount of deliberate practice in which these individuals have engaged. The argument that prodigy is mainly a result of nurture is not very sound because it is supported mainly by findings on adult expertise. These findings show at most that environmental factors are important to become an adult expert and not necessarily to become a prodigy. Although the role of commitment and hard work is necessary, nurture explanations fail to rule out the necessity for innate talent for high achievements.

The nature view on the other side argues that the prodigy phenomenon is first and foremost based on a strong biological hereditary component. Three kinds of arguments support some kind of innateness. Firstly, some studies indicate that practice alone does not guarantee the mastery of a domain. For instance, studies on music expertise have shown that the skills for piano sight-reading are facilitated by working memory and do not improve with increasing the number of hours of practice (Meinz and Hambrick, 2010). In the case of chess players, the number of hours necessary for becoming a master are highly variable and even thousands of hours of deliberate practice do not guarantee the mastery. Secondly, there are reports of high level performance achieved by children without any deliberate practice. Reports of children that achieved high performance in reading, number, drawing and music suggest that they had strong predispositions present prior to any deliberate practice (or at least not in the same way/extent as in adults). Thirdly, there are indications from twin behavioral genetic studies of music that the *rage to master* (strong intrinsic

motivation) is highly heritable. Recent proposals suggest that even the propensity towards “deliberate practice” has a genetic basis (Winner and Drake, 2018). Hard work or deliberate practice is also required for high-achievement, but it is considered that hard work depends on two factors: an inborn ability to make progress (without which children would likely be frustrated and give up) and a strong *rage to master* (Winner and Drake, 2018). These two factors are very likely determined genetically according to Winner and Drake (2018).

While the nature-nurture debate on high achievements (as well as prodigy, giftedness, talent or expertise) is ongoing, new findings from both camps reveal that the nature-nature dichotomy does not capture the multidimensional dynamics between the factors that lead to prodigiousness. Feinstein’s (2003) influential longitudinal study looked at British children from the 1970 cohort and assessed children at 22 months, 42 months, 5 years, 10 years and 26 years. Test scores from 22 months predicted the educational qualifications at the age of 26. The most important factor that predicted the relationship between test scores and educational qualifications was the socioeconomic (SES) background of the parents (measured as the parents’ level of education). A child with poor scores in the early test would be more likely to catch up if they would be raised in a wealthy or educated family, while a child raised in a poor family would be extremely unlikely to catch up. This study shows that a supportive environment has a decisive role for children’s development, especially for children who have low test scores at younger ages. This explains why it is so hard for prodigy children to rise from poorer backgrounds. Recent studies on intelligence and giftedness offer an updated view on the genetic basis of prodigy. Epigenetic results such as those of Plomin et al. (1994) indicate there are passive, active, or reactive interactions between dispositions and environment. Moreover, the genetic influence on cognitive ability appears to involve many genes, each contributing to small effects that are additive or multiplicative (Simonton, 1999). Simply, the innately gifted individual has been lucky enough to inherit cognitively beneficial versions of many genes.

Because data from genetic studies and from investigations of environmental influences are correlational and not causal, new interesting perspectives about development of high cognitive abilities come from neurocomputational modelling, for instance the work by Thomas (2018). First, the model presented by Thomas suggests that children’s early ability is not stable across development and that the performance in early development predicts only a small variance in the performance of the adults (see also the model of Simonton, 1999). Second, the model showed that individuals who scored high in early development were more likely to fall back in population rank in case their families had lower SES. Third, to be early identified as gifted, the model required that both intrinsic neurocomputational parameters and high-quality training environment to function at optimal levels. Moreover, the giftedness development was characterized by a fast rate of acquiring knowledge. Fourth, there were asymmetries between the influences on gifted and the delayed-performance children; a poor environment was not predictive of delay, but a good environment was predictive of giftedness. Unusual trajectories were not explainable by a single cause, but by interactions between multiple factors. Emergent accounts of performance (Simonton, 1999) suggest similar things; that giftedness can be impeded by the absence of any of the multiple factors (such as not having a rich supportive environment). This translates into the view that there are many ways to fail but few ways to succeed, which also reflects the small percentage of children that reach top achievements. Overall, to become a prodigy, a child needs all the genetic factors to translate into highly functional cognitive and physical functions in a highly supportive environment.

Determining the causal mechanisms for the prodigy phenomenon is a very difficult endeavour, and neurocomputational models with support for empirical studies seem to be one of the most viable solutions for future research. As described in the previous section, cognitive and developmental approaches help towards understanding how a child becomes a prodigy.

Neuropsychological Explanations

In terms of neural mechanisms and neurocomputational properties, giftedness and prodigy performance is the result of many small advantageous aspects of neural computation, potentially across multiple systems, which contribute to the development and maintenance of cognitive and physical abilities (Thomas, 2018). There is very little empirical research on the neuroscience of prodigy. Much of what is known about the neurological foundation of prodigies comes from giftedness research. Neuroscientific findings suggest that the brains of gifted children have different functionalities than the typical developed children. For instance, it has been proposed that gifted children have relatively enhanced structural, and hence functional, neurobiology in the prefrontal cortex regions responsible for cognitive control, and working memory (Geake, 2008). Other neuroscientific findings indicate that bilaterality is an important neurobiological characteristic of how information is processed by gifted people (Singh and Boyle, 2004). It has also been proposed that giftedness is a type of neural plasticity (Kalbfleisch, 2009, p 276). Increased neural plasticity might be the neurobiological basis of the overlapping sensitive periods proposed by Shavinina (2010). The exceptional accomplishments of child prodigies have also been discussed to be due to a heightened attentional control learned in early infancy. This attentional control originates through bidirectional connections of prefrontal-parietal cortex (center of working memory) and cerebellum (center of attention). It is suggested that at the base of prodigies’ exceptional memory is the increase in the ratio of cerebellum to cerebral cortex which boosts the efficiency of information processing in the cortex (Vandervort, 2009). While all these theories might be valid, to date there is no neuroscientific empirical study made specifically on prodigy children.

Prodigy and Creativity

Are prodigy children creative? This is a particularly interesting question as it is highly disputed whether we can talk about creativity in children at all (Glăveanu, 2011). Moreover, the relationship between intelligence and creativity has not yet been elucidated. The

relationship between creativity and prodigy has been amply described in the last edition of this encyclopedia. Here we will address the question from a slightly different angle. Generally, to be considered creative one must *produce relevant and effective novel products*, which is not what prodigy children are defined by. One way to understand to what degree prodigy children are creative is by analyzing two broad categories of accomplishments: expertise and creativity. Some researchers consider that creative people are makers who have transformed an intellectual or practical domain or an artistic way of expression a field, while experts are masters who have perfected their respective trades to an extremely high level. Based on this distinction, a prodigy child shows high levels of expertise and not creativity, at least not to the extent of transforming a field or way of expression. This is not to say that prodigy does not manifest any creative potential, on the contrary. One thing that prodigy children and creative people have in common is that they produce surprise and get admiration from people and socio-cultural validation. The difference is that, while prodigy children get a unanimous and instant admiration from society, some products of creative people get a harsher scrutiny, for longer periods of time, with a strong culture-dependency (see Glăveanu, 2011). Thus, this external validation might not regard the same capacities.

Final Thoughts/Intriguing Questions on the Phenomenon of Prodigies

Should we disentangle the effects of nature from those of nurture? Or should we give up this debate, just like some researchers suggest for developmental psychology in general. This latter idea is based on all the recent research that shows that neither nature nor nurture can work in isolation. In other words, genes need an appropriate environment for optimal gene expression, while taking advantage of the environmental opportunities need some innate potential. As such, we should talk about interacting factors that are not on a continuum, but on a spiral, and which could be modeled with dynamic systems theory.

Should we necessarily link the prodigy phenomenon to creativity? No: creativity is an elusive concept itself and maybe it should remain a rare phenomenon. To put it in the words of Beck et al. (2016, p. 9): "It is clear that we do not yet have the answer to why some children solve innovation tasks and others do not. Indeed, we may now also be worried about whether they even are innovators." As such, just like the literature shows so far, we have to consider as prodigies children with early expert performance, regardless of their creative outcomes.

Should we deliberately accelerate development? Extreme supporters of environmentalism are in favor of an "absurd environmentalism" (Detterman et al., 1998), the essence being that if you put enough resources and energy into any child development, they can achieve anything. This view, highly spread in the media, can give unrealistic aspirations to parents and what their children can achieve. If the innate basis is not in place, pressures on the children towards high achievements are detrimental to their development (Abeles, 2015).

Acceleration did not provide much success so far (Blakemore and Frith, 2005), and this may be an indirect proof for some kind of innateness. Until there is enough data that acceleration works and in what conditions, one should be careful as to the demands one puts on a particular child. In other words, we should allow each child to reach his/her potential, regardless if it is a prodigy child or not.

Introduction: Linguistic Creativity and Creative Language

Language is fundamentally and inherently creative because every utterance spoken and word written is unique in some manner. In other words, within the reasonable confines of a language's syntax, speakers have almost limitless options when choosing not just the words they will use in an utterance, but also the ordering of those words, the way they deliver those words (e.g., tone, volume), and other paralinguistic information associated with those words (e.g., hand gestures). Every instance of language use is thus a representation of creative expression. Because psycholinguistics is a discipline devoted to understanding how humans produce, process, and comprehend language, it is, by extension, an investigation into a creative phenomenon.

This entry will review psycholinguistic investigations into what is known as *creative language* from the perspective of cognitive linguistics. Cognitive linguists are concerned with how language, thought, and behavior are shaped by one another, such as how features beyond linguistic structure (e.g., individual cognitive differences) influence language use, or how language may help researchers better understand how humans perceive and categorize the world (e.g., through conceptual metaphor). Accordingly, many cognitive linguistic studies employ psycholinguistic methods in order to explore different questions related to language and thought. As will be seen below, these methods have been particularly favored by linguists who investigate creative language, as they are used to determine whether creative and non-creative language significantly differ in terms of human behavioral responses (e.g., reading times, eye movements, sensibility ratings).

In order to gain a better understanding into this line of research, this entry will first describe general characteristics of the field of psycholinguistics, define creative language, provide an overview as to how different types of creative language have been explored using psycholinguistic methods, and finally suggest how these explorations can be aligned with more general examinations of creativity from the perspective of psychology.

Psycholinguistics

Psycholinguistics is a marriage between psychology and linguistics devoted to investigating connections between psychological processes and language use. Researchers in psycholinguistics are therefore varied in their approaches and research interests and investigate a broad number of research questions related to language, such as processing, production, storage, impairment, acquisition, and more. Psycholinguists have developed a number of specialized experimental tasks which measure behavioral responses to linguistic stimuli, including reading times, eye movements, physical responses, electrical activity in the brain, and so on. Data in these experiments are typically (but not always) measured using extremely small units, such as the number of milliseconds it takes to press a button in response to linguistic stimuli, or the distance that a subject's eyes move while reading different words in a sentence.

One of the goals of psycholinguistic research is to develop representative models for how language is processed and stored in the brain. There have been an overwhelming number of psycholinguistic models developed over the past decades, and these models are divided into those which explain written language comprehension, spoken language comprehension, spoken production, and so on. These approaches are further segmented into models explaining the lexicons (i.e., the mental representation of words and concepts) of monolingual versus multilingual language users. Modern psycholinguistic evidence suggests that language is stored in a probabilistic network of interconnected features, including linguistic structure (e.g., pronunciation, syntax), concepts, and other linguistic information which simultaneously activate and interact with one another during language use.

Creative Language

Recognizing that language production is an inherently creative act, there is a difference between the creative process of language production and the production of language that is itself considered creative. This distinction appears small at first but is fundamental to psycholinguistic investigations of creative language taken up here. From this perspective, creative language is defined as any sort of manipulation to language that results in an interpretation that is unexpected or otherwise unique (Gerrig and Gibbs, 1988). When describing creative language, there is usually a contrast made between the surface-level meaning of an utterance, also referred to as the *literal* meaning, and the alternative, creative meaning of an utterance. Generally, the creative meaning of an utterance cannot be inferred through a semantic decomposition of the literal, surface meaning of the utterance, but instead requires some additional cognitive processing in order to decode the intended meaning. Two of the major types of creative language that have attracted a large amount of attention in this area are figurative language and humor.

Figurative Language

Figurative language is a broad category of language that includes metaphor, idiom, verbal irony, satire, and more. Of these different examples of figurative language, two have received extensive investigation using psycholinguistic methods: metaphor and verbal irony.

Metaphor. Metaphor is the most widely studied form of figurative language, and the one most closely associated with language and thought. This is primarily due to work in Conceptual Metaphor Theory. According to this theory, conceptual metaphors are said to be not just an example of linguistic creativity but are reflective of fundamental processes behind human thought. Specifically, this theory posits conceptual metaphors are representative of the system employed by the human mind to categorize and understand different entities in the world. Conceptual metaphors are usually described using an *A is B* formula, where a target entity *A* is re-categorized by placing it into a different conceptual domain *B*. This re-categorization is completed when some, but not necessarily all elements of the source domain (*B*) are transferred to the target (*A*), which provides new ways of interpreting and understanding the target entity. For instance, in the conceptual metaphor *lawyers are sharks*, abstract elements of sharks (e.g., predatory, dangerous) are mapped onto concrete understandings of lawyers, so that the basic understanding of a lawyer (i.e., a person trained in the law) is adjusted to also include new concepts related to sharks (i.e., a person trained in the law who is also ruthless and predatory). Conceptual metaphor is thus an incredibly efficient way to communicate meaning because it allows for the expression of difficult concepts in a relatively concise yet vivid manner (see Metaphors).

Verbal Irony and Sarcasm. Verbal irony (i.e., spoken irony, as opposed to situational irony) is another widely investigated form of figurative language. Theoretical definitions of verbal irony have continuously evolved since the oppositional theory of irony first defined verbal irony as an utterance which means the opposite of its literal form. For instance, if a bleary-eyed office worker arrived unenthusiastically to work on a Monday morning, she might quip “*I love Mondays.*” The oppositional account of verbal irony considers this utterance as ironic because it is clear that the speaker actually means the opposite of what she said (i.e., that she does not in fact like Mondays). However, this definition of irony is unable to account for ironic utterances that cannot be reinterpreted as the opposite of their literal meaning. For instance, a frustrated teacher exclaiming “*I love it when you’re on time*” when a student arrives late to class does not actually mean the teacher enjoys it when the student is late, but the utterance is nonetheless ironic in that situation because of the opposition between what was said, the context of the situation, and the more appropriate meaning. As such, the definition of verbal irony has been refined by scholars over the past several decades to now describe irony as an utterance that is both inappropriate yet relevant in a particular context (Attardo, 2000).

Humor

Much like figurative language, verbal humor (i.e., humor delivered through language) is a broad category and includes essentially any example of language that evokes a sense of mirth. Thus, while there are purposeful examples of verbal humor, such as canned jokes, puns, and other forms of wordplay, almost any utterance (including figurative language) can be perceived as humorous in a particular circumstance. Regardless of humorous intent on the part of the speaker, the process of humor comprehension has been typically described as the resolution of some form of incongruity among linguistic form, semantic meaning, context, and pragmatic knowledge. Resolution of this incongruity, such as recognizing the double-meaning of the word *coat* in the pun *the freezing painter hurried to put on a second coat* is where the sense of mirth and humor is said to arise.

Psycholinguistics and Creative Language

There has been a historic tendency for researchers and teachers in language and linguistics to treat figurative and humorous language as a deviation from the ostensibly normal, economical, and strictly communicative function of non-creative language (Glucksberg, 2001). Thus, it may not be surprising that some researchers interested in studying creative language were motivated to develop psycholinguistic models aiming to explain how creative language is produced and understood as an alternative process to non-

creative, (supposedly) standard language use. Accordingly, much of the early psycholinguistic research into creative language carried an assumption that creative language is somehow handled differently in the brain when compared to non-creative language (a point that has been long and sharply contested in the field but continues to persist). For both figurative language and humor, early models and experiments were designed to test predictions of the Standard Pragmatic Model.

The Standard Pragmatic Model. The Standard Pragmatic Model (SPM) represents a starting point for many theoretical descriptions for how hearers process and comprehend both humorous and figurative meaning. According to the SPM, figurative meaning is the result of a re-interpretation of a figurative utterance based on the pragmatic context within which it is stated. To understand the figurative meaning of an utterance, a hearer must first interpret the literal meaning of an utterance, reject the literal meaning based on contextual information, and then compile a new, figurative meaning, based on their understanding of the speaker's pragmatic intent and the surrounding context. Therefore, the SPM assumed that figurative meaning was dependent upon an initial literal meaning, which would suggest figurative meaning comprehension should take longer and require more cognitive effort than literal meaning comprehension, as multiple meanings must be considered.

Psycholinguistic Studies of Creative Language

Partially motivated by the predictions made by the Standard Pragmatic Model, early psycholinguistic research into figurative language comprehension was concerned with answering whether or not a hearer must first comprehend and then reject the literal meaning of a figurative utterance before arriving at the figurative meaning. The general approach of these experiments was to present research participants with linguistic stimuli that was controlled to bias either a literal or non-literal interpretation and then record differences in behavioral responses to that stimuli. For example, a researcher might show participants the phrase *He is a good soldier!* alongside information describing someone in two different ways: as a member of the military or as a hard worker. These two different descriptions would thus bias the same sentence to be read either metaphorically or non-metaphorically.

The researcher would then measure and compare behavioral responses among different participants to the same sentence in these two contexts. In general, slow behavioral responses would be taken as evidence that a participant expended more cognitive effort to decode the sentence, and therefore may be indicative of the two-stage processing predicted by the SPM if the metaphorical version took longer to read. In other words, the longer times would suggest that the participant first had to decode the literal meaning of the sentence "*He is a good soldier!*", compare that meaning to the context of the sentence (e.g., talking about the man being a hard worker), reject the literal meaning, and then search for an alternative and plausible meaning (namely, that the man is being compared to a soldier for similar qualities that are reflective of a good or hard worker, with the assumption that soldiers are generally perceived to perform difficult tasks and must therefore work hard).

Metaphor Processing. Metaphor was studied extensively by cognitive linguists using psycholinguistic methods. The consensus is that understanding metaphorical meaning requires no more cognitive effort than understanding non-metaphorical language. Specifically, research demonstrated conventional (i.e., familiar and commonly used) and novel (i.e., uniquely coined and infrequently encountered) metaphors take no longer to process and understand when compared to their literal counterparts. Additionally, metaphorical meaning is activated even when metaphors are placed in literal biasing contexts, suggesting metaphorical meaning is primary and interpreted first when hearers encounter metaphorical utterances. There is therefore strong evidence suggesting that metaphorical meaning is not processed any differently than non-metaphorical meaning, even if the meaning of a metaphor is not a function of the surface meaning of a metaphor's linguistic form.

Explanations for this effect include links to Conceptual Metaphor Theory, which suggests that metaphorical comparisons are representative of how the human mind conceptualizes the world (see above), and therefore the default state of thought may in fact be metaphorical, which would allow for effortless interpretation of figurative meaning from metaphorical utterances. At the same time, many metaphors are so entrenched in language they have been described as dead, suggesting that any literal meaning which used to exist in a particular metaphorical phrase is no longer the primary meaning.

Verbal Irony Processing. Similar to metaphor, verbal irony has also been extensively studied by cognitive linguists using psycholinguistic approaches. Unlike metaphor, the resulting models and understanding of how verbal irony is processed has been less conclusive, and debates remain regarding whether verbal irony comprehension is primarily a two-stage process, whether the figurative meaning of an ironic utterance can be directly accessed in a manner similar to metaphorical meaning, or some combination of both. Based on psycholinguistic experiments of ironic language processing, two main theoretical models have been produced: a direct access view and a salience first view. The direct access view is based on Gibbs (1986) and other studies demonstrating no significant differences in reading times for ironic utterances and their literal counterparts and that manipulations made to the context of an utterance significantly predict comprehension and reading times. Specifically, Gibbs (1986) found that as the surrounding linguistic contexts were changed to bias ironic interpretations of ironic statements, participant reading times became quicker, and they were better able to remember the ironic utterances. Gibbs (1986) argued the contextual information present in his examples allowed for the direct processing of ironic meaning, and that the probabilistic incorporation of contextual information during reading is how the meaning of any utterance, literal or figurative, is obtained. In other words, the direct access view does not assume any single utterance contains an inherent, decontextualized meaning, and that the interpretation of figurative meaning requires processes no different than the interpretation of literal meaning, rejecting the predictions of the SPM.

The assumptions put forth by the SPM were also called into question by Giora (1997), who believed the divide between literal and figurative meaning overlooked the actual linguistic mechanism responsible for differences in processing time: the role of salience. Initially proposed to explain the processing of metaphor, Giora (1997) argued the most salient meanings of a phrase or utterance are always processed first, regardless of contextual influence. This is because salient meanings are frequent, familiar, conventional, and thus represent prototypical or standardized meanings. Importantly, these features are *graded*, in that their relative strengths determine how salient a particular meaning is to a particular person. Salient meanings are stored in the mental lexicon, allowing for quicker access and retrieval when compared to novel meanings that must be computed in the moment. Salient meanings are not specific to literal or figurative language and are so strongly activated they can mitigate the effects of prior context biasing a non-salient meaning. This feature, according to Giora (1997), is what explains the results of research showing no significant differences between processing times for metaphor, because metaphorical meanings are encoded into the lexicon. However, when hearers encounter figurative language representative of a non-salient meaning, they must first interpret the literal meaning of the utterance in order to determine the figurative meaning. In this manner, Giora's Graded Salience Hypothesis (GSH) subsumes both the direct access and Standard Pragmatic Model of figurative language processing. When meanings are salient, they can be directly processed without needing to consider alternative meanings (i.e., direct access view) because they are readily available in the lexicon. When meanings are not salient, the literal meaning is first interpreted, rejected, and ultimately replaced with the intended figurative meaning, derived from contextual clues (i.e., the Standard Pragmatic Model).

Humor Processing. Compared to research into figurative language, there have been relatively fewer studies investigating humor processing using psycholinguistic methods. Similar to the figurative language studies discussed above, theoretical models of humor processing were built on assumptions that humor comprehension is the result of a two-stage process involving the resolution of an incongruity between an intended and humorous meaning of a joke. However, several more recent psycholinguistic studies suggest that humor does not always require a two-stage process of incongruity resolution. For example, one study measured participants' eye movements as they read jokes or non-humorous proverbs that were said to be either from a comedian or a politician (Mitchell et al., 2010). This study found that participants' eye movements could be predicted depending upon whether the joke was framed as coming from a comedian or a politician. Essentially, if participants were reading a text from a comedian, they spent more time reading the initial framing or setup of the joke in anticipation of the punchline, which resulted in quicker processing of jokes when compared to the proverbs. In other words, if the participants were expecting humor, they prepared themselves to process any subsequent humor and thus overcame any additional demands the resolution of the incongruity might make upon their cognitive processing of the text.

A different study compared eye movements for participants who read jokes and non-humorous texts that nonetheless required some form of reinterpretation of meaning (Ferstl et al., 2016). For example, one text requiring non-humorous revision began with a judge asking a man if he had anything else to say, prompting a mental image of a courtroom scenario. The man's reply however, which was a reminder that the judge had an extra appointment the next morning, prompts a revision of the initial meaning into a new meaning (e.g., that the man is not a defendant in a court case but rather an assistant to the judge). The results from this study reported significantly fewer re-readings of the initial framing of the text if the text was humorous versus non-humorous. Ferstl et al. (2016) interpreted these findings as evidence that when a revision (or resolution of an incongruity) results in humor, the reader recognizes the humorous reaction as a confirmation of the resolved incongruity and does not need to further consider the initial meaning. For the non-humorous texts, the meaning revision resulted in significantly more re-readings of the prior context, suggesting that a non-humorous resolution is less acceptable to participants. Although Ferstl et al. (2016) claimed these results cast doubt on the need for a two-stage resolution process during humor comprehension, their results more strongly suggest that humorous meaning assists readers when they encounter incongruity (but does not rule out the need for two-stage processing).

Direct Connections to Creativity. Despite studying a creative product, many language researchers do not make connections between creative language and the larger construct of creativity as a cognitive individual difference. And the converse is equally as true; many studies of creative ability and creative potential neglect the role of creative language. There are exceptions to this – humor has been identified as a facilitator of creativity, and at least two studies have reported results suggesting the ability to produce higher quality metaphors is an index of creative ability (Beaty and Silvia, 2013; Silvia and Beaty, 2012). Another study examined the influence of sarcasm use (sarcasm is a common form of verbal irony which is usually negative in tone) on the ability to solve explicit tests of divergent and convergent creativity (Huang et al., 2015). In this study, Huang et al. (2015) hypothesized that both sarcasm use and creative ability relied on a similar cognitive construct (i.e., abstract thought). In their first two experiments, Huang et al. (2015) asked participants recruited from the internet to produce, comprehend, or recall past instances of sarcasm (or were assigned to a non-sarcasm control condition) before completing tasks designed to measure creative ability (i.e., the Remote Association Task and the Duncker Candle Problem). Regardless of how sarcasm was being used, exposure to sarcasm significantly boosted participants' performance on subsequent tests of creativity when compared to the control group. In Experiment 3, Huang et al. (2015) replicated the first two experiments using human subjects in a laboratory setting, which enabled them to include more complex tests of creativity (e.g., Olive in a Glass problem), and also measure participants' abstract thought using questions from a survey. Crucially, participants completed the survey questions *after* being exposed to sarcastic or non-sarcastic stimuli and *before* completing tests of creative ability. The results reported abstract thought was significantly higher for participants who produced and listened to sarcastic utterances when compared to the control conditions, and also that participants exposed to sarcasm outperformed participants in the control conditions on tests of creativity. Huang et al. (2015) took these results as evidence suggesting that sarcasm boosted abstract thought, which in turn increased creative ability.

Summary and Suggestions for Future Research

In general, the psycholinguistic research investigating creative language has proceeded by testing whether creative language requires a two-stage meaning interpretation before arriving at a figurative meaning. While some types of creative language appear to require no more processing time than non-creative language (e.g., metaphor), studies of verbal irony continue to produce evidence suggesting verbal irony takes longer to process than equivalent, non-ironic utterances, but also that other contextual features, such as familiarity or negated language, can result in verbal irony being processed just as quickly as non-irony. One commonality of this research, perhaps best highlighted in the research on humor comprehension, is that a two-stage process of creative meaning resolution is heavily dependent upon contextual features that are partially linguistic and partially external to linguistic forms. Thus, explanations for creative meaning comprehension tend to converge towards current psycholinguistic explanations for the comprehension of any utterance. It may indeed be the case that the same processes are at work when one is comprehending a creative or a non-creative utterance, and instead of a qualitative difference between two different processing models, it is instead a quantitative difference which depends upon a number of different features that continue to be highlighted by current research in the field.

There still remains a wealth of research questions that can be investigated in order to bring linguistic and psychological conceptualizations of creativity closer together. For instance, experiments investigating whether subjects with different creativity scores (e.g., divergent thinking test performance) process or produce creative language differently would be a relatively straightforward first step towards linking these two fields, as would testing whether completing creativity tasks affects subsequent performance on figurative language processing or production. At the same time, although figurative and humorous language are considered to be creative instances of language use, some examples of creative language are highly conventionalized and ubiquitous in everyday conversation, suggesting they may be more routine than creative. It would therefore be useful to conduct studies gathering layperson perceptions of creativity in creative language using constructs developed by psychology researchers (e.g., ratings of novelty and effectiveness). This research would align well with current pursuits in the field of creativity which have identified specific linguistic features predictive of creativity scores on divergent thinking tests.

As mentioned earlier, there is a fine distinction between being creative and using creative language, and future research investigating potential relations between these two notions could serve to benefit researchers in all fields studying creativity from multiple perspectives. By obtaining a better understanding of how psycholinguists have operationalized and studied creativity, researchers in psychology can gain additional perspectives and insight into creative language, which may serve to expand efforts in the field to better understand creativity as a whole.

A commonly held belief is that Asian cultures are less creative than the Western culture, and such a belief was explicated in a book, entitled *"Why Asians are Less Creative than Westerners"* (Ng, 2000). Another evidence comes from the Global Innovation Index (GII), released annually by the World Intellectual Property Organization (WIPO), an agency of the United Nations since 2007, ranking countries by their capacity for and success in innovation. Calculation of GII comes from a variety of factors including both subjective (such as a survey of global CEOs) and objective data derived from several sources such as a number of scientific and technical publications, international patent and other intellectual properties, Global R and D expenditure (GERD), and innovation policies. In all past 11 reports, only one Asian country, Singapore consistently made it into the top 10 most innovative countries list. The other nine were all from Western Europe and North America. Four other Asian countries and economies, Israel, Japan, South Korea, and Chinese Hong Kong, were in and out of the top 10 list, and have gradually made it into the next tier list (typically between 11 and 15) (Cornell University et al., 2018). Although creativity does not equal innovation, at least in the eyes of global businesspeople, creativity in Asia has fallen behind of creativity in the West.

Are Asians less creative than Westerners? Answers to this question are anything but simple. One crucial difficulty lies in the definition of creativity. A widely accepted definition for creativity is its dual feature, being both original and appropriateness (also called value or effectiveness; see Runco and Jaeger, 2012 for reviews and Definitions of Creativity). However, both originality and appropriateness are relative terms and rather subjective, which depends on who (the field) judges the creative products and which domain (domain) the products belong to (Kaufman and Baer, 2012). Besides domain and field (or de facto gatekeeper), the cultural context in which the person lives and the products being evaluated also play a critical role in evaluating creativity.

This subjective nature of creativity in its conception may suggest that the kind of creativity emphasized and fostered in Asian cultures may be different from the ones explored and measured in the West. It may also imply that the Asian notion of creativity has not been fully recognized by the current society; therefore, lead to perceived inferiority in creativity by the public and scholars alike. This entry primarily focuses on examining the concepts of creativity in the context of Asian cultures, from two bodies of literature, explicit theories and implicit theories of creativity, to explore how people in Asia conceptualize creativity and whether or not their conception of creativity lead to lack of recognition of Asian creativity in today's world.

Explicit Theories of Creativity

Explicit theories refer to theories explicitly proposed by psychologists and other social scientists to examine the concept of creativity. Most explicit theories of creativity come from English-speaking countries such as the United States, based on studies of people from the West. In a review to 42 explicit definitions and 120 collocations of creativity, Kampylis and Valtanen (2010) traced the origins for the word "creativity" in English and found that word first appeared in printed form less than 125 years ago. Many explicit theories of creativity have been proposed, to examine the nature of creativity, most of which are from the United States. There are a few theories derived from Asian cultures.

Through examining both Confucian and Taoist philosophical documents and research literature on contemporary Chinese views of creativity, Niu (2012) proposed that the usage of a new concept, called “contextual creativity or co-creativity” (or *creatio in situ*), as a contrast to the western conception of creativity, which is rooted in the Biblical idea of God’s creation, create from nothing (or called *creatio ex nihilo*). She further illustrated the difference between the Chinese conception and the Western conception of creativity, and concluded four unique characteristics differentiate Chinese co-creativity to the Western concept of creativity. They are: (1) although both *creatio in situ* and *creatio ex nihilo* share the same meaning for “creation of the world,” Chinese co-creativity recognizes the significant role human beings play in the creation of the world and human civilization, and emphasizes that every human being has the potential to be creative; (2) whereas the Western notion of creativity lies in the power of the creator, Chinese co-creativity attributes creative process as a result of the interaction between the creator and the environment: therefore creativity is always contextual and interactive in the Chinese context; (3) although novelty is important for the Chinese conception of creativity, appropriateness, defined as fitting to the changing context, is viewed as more important in the Chinese conception of creativity; (4) creativity is also viewed as domain specific. Again, everyone has the potential to be creative in the domain of their own choice, which can range from an everyday field such as culinary arts to more prestigious and scholarly disciplines such as literature.

Influenced by both Confucian and Buddhist beliefs, traditional Japanese notions of creativity present a slightly different approach than traditional Chinese, that is, the emphases of the importance of nature and the universe as a source for creativity. Creativity was also viewed primarily in traditional art domains in Japan, such as the green tea ceremony, dance, traditional flower arranging, and calligraphy. When engaging in these activities and ceremonies, people can achieve “pure expression” or the highest level of creativity through meditative process of repetition and perfection of technique (Nakagawa, 1991).

There are similarities between Indian and Japanese conceptions of creativity. Rooted in Hindu philosophy, especially the Samkhya school of philosophy, the Indian view of creativity stresses the process of making connections between a person and the primordial realm, or perfect knowledge through the practice of yoga and meditation, which is called the process of self-actualization, self-fulfillment, and self-realization (Raina, 2004). The Indian word for creativity is *pratibha*, or intuitive creative power, meaning a flash of light, a revelation, a supra-rational or a beyond rational appreciation, grasping truth directly, and leading to the realization of new meanings (*navonavonmesasalini pratibha*) and the creation of something that had no prior existence (*apurvastunirmanksama prajna*). The goal of engaging in the creative process is to seek joy, to reach the highest standards in every phase of life, to discover the best of oneself, or to reach extraordinary achievement in any field of human endeavor, driven solely by strong and powerful inner urges without external prodding (Misra et al., 2006).

Taken together, explicit theories from Asia provide unique perspectives on the concept of creativity that differ from what Western scholars have proposed. Having multiple philosophical roots, namely, Confucianism, Taoism, Buddhism, and Hinduism, creativity is understood in multiple perspectives. First, the creative process as a connection between the individual and universe, and everyone has the potential to be creative through discovery of one’s potential or meditation. Second, creativity is viewed as excellence and perfection and can be achieved via purposeful learning or mediation. Thirdly, creativity is viewed as contextual and domain-specific, and mostly exhibited in the art and literature domains. Lastly, there is a greater emphasis on the linkage between old and new; therefore creativity conception in Asia is more evolutionary than revolutionary.

Implicit Theories of Creativity

Implicit theories refer to studies examining underlying beliefs of ordinary people of a society regarding their everyday understanding to certain phenomena, which allow lay people’s views to be integrated into scientific discourse.

Results from the earliest studies on implicit theories of creativity (primarily using American samples) commonly link creativity to characteristics of an ideally creative person such as being intelligent, open-minded, imaginative, energetic, active, motivated, willing to take a stand, inquisitive, curious, adventurous, ambitious, confident, determined, enthusiastic, free spirited, non-conformist, individualistic, assertive, daring, artistic, having good aesthetic taste and having a sense of humor (Runco, 1984; Sternberg, 1985). An environment with choices, the acceptance of ideas, the boosting of confidence, and the stimulus of intrinsic motivation are believed to be conducive to the development of creativity.

Studies from Asian cultures (such as China, Japan, Korea, and India), have shown that although Asians perceive some core personal characteristics, such as being intelligent, imaginative, independent, open-mindedness, to be important features for creativity, they also have different emphases.

Studies using Chinese samples from Mainland China, Hong Kong, Taiwan, or Singapore, indicated that some personal characteristics, such as “having a sense of humor” and “having aesthetic taste,” are deemphasized in the Chinese conception of creativity. In contrast, other characteristics, such as being honest, responsible, self-discipline, selflessness, and making a significant contribution to society are linked to creativity (Chan and Chan, 1999; Rudowicz and Yue, 2000).

Similar to findings from Chinese societies, studies from India revealed a greater emphasis on relational, social, and interpersonal aspects rather than personal, cognitive, and utilitarian aspects of creativity among a sample of Indian college students (Panda and Yadava, 2005). Creativity in Indian culture is also viewed as domain-specific (Misra et al., 2006) and as seeking connection between inner and outer existence. Being able to re-interpret traditional ideas in the domain of music and literature, making original contributions, and being able to synthesize and integrate are perceived as chief characteristics of creativity in the domain of sciences. Overall, compared with the Western notion of creativity, the Indian conception of creativity emphasizes affective, social,

and intuitive elements, and places greater value on intuition, insight, introspection, the ability to look inwards, open mindedness, and on creating a relationship between external surroundings and internal processes (Sen and Sharma, 2011).

Studies of Korean conception of creativity also demonstrated some cultural variations. Hong and Kang (2010) studied conceptions of creativity between Korean and American secondary science teachers, and found that Korean teachers tended to consider ethics as a more important criterion for judging creativity than the US teachers. They also placed more emphasis on the importance of teaching strategies such as providing students with more thinking opportunities in class in fostering student creativity while the US teachers emphasized the importance of environmental or emotional support. Lim and Plucker (2011) also reported that although Koreans have a similar conception of creativity to Westerners, they tend to associate creativity with some negative personality traits such as deviance, suggesting that being creative may not be socially desirable in the Korean cultural context.

Direct evidence of Japanese implicit theories of creativity is sparse. In one study, Zhou et al. (2013) studied Japanese teachers' implicit theories of creativity and found that production of a large number of ideas (fluency of divergent thinking) was not viewed as important in characterizing student creativity. Instead, coming up with original ideas and refinement of the ideas were viewed as more important. There is also a greater emphasis on traditional arts in the Japanese conception of creativity (Ramos and Puccio, 2014).

Interestingly, there are a few cross-cultural studies that directly compare implicit theories of people from East and Southeast Asia and the United States. For example, Ramos and Puccio (2014) studied implicit theories of creativity between Americans and three main groups of ethnic Singaporeans (Chinese, Malays, and Indians). They asked participants to rate the importance of creativity in two types of peoples, innovators (those who break the rules and create their own rules) and adaptors (those who follow the rules), as well as their perception to creative individuals. The results showed that both Americans and Singaporeans listed thinking out of the box and being new, innovative, and unusual as being important to creativity. Creativity was also perceived to be associated to Kirton's innovative cognitive style, rather than the adaptor's cognitive style. Cultural variation existed only in the top categories, in which Americans and Malay Singaporeans tended to associate creativity with the arts or with being artistic, whereas Chinese and Indian Singaporeans tended to emphasize being new, innovative, and thinking out of the box as defining creativity. This lack of emphasis on being artistic or with having aesthetic taste in Chinese people was consistent with other studies of the Chinese conception of creativity (e.g., Rudowicz and Yue, 2000). Overall, the study concluded that although a more collectivist oriented culture, Singaporeans share similar conceptions of creativity to Americans in which seeking innovation and breakthrough are highly valued. They attributed this lack of cultural variation in people's implicit theories of creativity to Singapore's national desire for improving its citizens' creativity and to learn from the West for the continued growth of its economics.

Tang et al. (2014) did a study comparing American and Chinese students' implicit theories of creativity in computer sciences. They found that both American and Chinese samples described creativity in computer sciences as: (1) smart/effective, (2) outgoing, (3) thinking originally, and (4) unsociable. Cultural differences were exhibited in the relative importance of each of the four factors in the conception of creativity: whereas American participants rated being smart/effective and outgoing more important than their Chinese counterparts. Chinese participants rated having creative thinking as being more important in evaluating creative computer scientists than their American counterparts. Tang, Baer, and Kaufman speculated that this cultural difference could reflect a strong desire to catch-up within Chinese laypeople's view of creative thinking. No cultural differences were observed on the factor of "unsociable," which was inconsistent with findings from another study in which creativity was rated as relatively undesirable for the Chinese (Chan and Chan, 1999). They concluded that, at least in the domain of computer sciences, people from both cultures hold similar implicit theories of creativity. They believe that cultural influences on implicit theories are more complex than explicit theories have suggested.

Paletz et al. (2011) asked American, Chinese, and Japanese college students to generate words and phrases associated with creative acts and behaviors of individuals. The entire list was coded as either external (that is, needing to involve others, such as social interaction, sports, and cooperation), internal (that is, can be done individually, such as thinking and designing), neither external nor internal, or both. The results revealed that both Chinese and Japanese students showed preference for the external, whereas Americans showed a preference for the internal, a direct evidence that Asians place a greater emphasis on social aspects than their American counterparts.

Conclusions

In viewing both implicit and explicit theories of creativity in Asia, what can we conclude the defining features of creativity among Asians? And importantly, what are some differences between Asian than the Western conceptions? Here are some highlights:

Individual Versus Social

It is clear that western conception of creativity places a greater emphasis on individual characteristics of creative individuals, such as having specific personality traits and cognitive styles. Asians place a greater emphasis on social aspects of creative acts or products, such as teamwork and support from others (evidence from Korea), interaction between the creator and his or her environment (evidence from China), as well as having significant contributions to the society (evidence from China, Korea, and India). The social aspect of creativity is unique in the conceptions of most Asian countries including China, India, Japan, and South Korea. In other words, compared to the people from the West, Asians values social contribution of the creators more than individual characteristics

of the creators. This is perhaps the most salient departure between the two conceptions, and it is also consistent with the worldviews, one being individualist in nature and the other collectivist.

General Versus Contextual

Creativity was viewed as a general cognitive ability—divergent thinking—in the West and only recently has been viewed as domain-specific. On the contrary, as illustrated in this chapter, rooted in their perspectives and philosophical traditions, creativity has been continuously viewed as contextual and domain-specific in Chinese and Indian cultures. Evidence from studying people's implicit theories also supports the idea that creative artists and scientists are viewed as having different traits and styles from the Asian perspective, and should be dealt with differently.

Novelty Versus Appropriateness

Both cultures view novelty and appropriateness as defining features for creativity, but do people view them equally in judging creativity? The literature has provided an inconclusive answer to this question. Studies of explicit theories confirm a general stereotype that Westerners place more emphasis on novelty and Asians place more value on appropriateness; although appropriateness is a relative term, and people from different cultures may perceive appropriateness differently. More studies are needed to further examine cultural differences in the novelty-appropriateness dimension of creativity conception.

Revolution Versus Evolution

Whereas Westerners often view creativity as a breakthrough between new and past products (a revolution or radical change), Asians often view the importance of linkage between past and new (an evolution or an incremental change).

The Role of Intrinsic Versus Extrinsic Motivation

Western theories have emphasized the importance of intrinsic motivation to creativity. According to Amabile's (1996) componential theory, creativity is driven by intrinsic motivation; any constraints from outside such as rewards, deadlines, observation, peer critiquing, and even explicit coaching would diminish people's intrinsic motivation thus negatively influencing creativity. However, the theory has yet to be fully examined in Chinese culture, especially in its relationship with the other domain specific aspects of creativity.

Lab experiments examining motivation and creativity in the Chinese context have also shown mixed results. Generally, intrinsic motivation seems to help student creativity, although extrinsic motivation is not seen as a negative. For example, in one study, Niu and Liu (2009) found that the creativity of Chinese students increased when they were explicitly told the goal of the creativity and the means to attain creativity. Chinese participants are also more affected by special instructions that explicitly encourage them to be creative, perhaps because of the need for "permission" to be creative (Niu and Sternberg, 2003).

After examining the literature of explicit and implicit theories of creativity, one notable conclusion is that conceptions of creativity are inseparable from cultural values and cultural practice. Rooted in collectivist and interdependent-self cultural traditions, Asians tend to put collectivist interests and societal needs above their individual interests. Historically, creativity was more likely to be expressed in art and literature. These characteristics are supported by studies from both explicit and implicit theories of creativity.

There is a discrepancy between the explicit and implicit theories in terms of relative importance of novelty and appropriateness in creativity. Explicit theories suggest that because of the constant consideration of collective interests, appropriateness is weighed more and originality less in judging creativity among Asians, compared to Westerners. Evidence from implicit theories, however, do not support such a claim. One interpretation is that influenced by Western cultures; contemporary Asians adopted a more Western notion of creativity in their conception of creativity. It is important to note that most studies of implicit theories were conducted in major cities and used university student samples, where the culture is more westernized or globalized. Moreover, there is an increasing demand for creativity in scientific and technological domains in Asia, where the definition of creativity seems more universal than cultural-specific in nature. It is also an area many Asians feel they are behind the West. Nevertheless, some unique characteristics for Asian conceptions of creativity highlighted in this entry can enrich people's understanding of the nature of creativity and may provide some new perspectives to nurture individual creativity.

Introduction

Making cross-cultural comparisons is by no means an easy task and making cross-cultural comparisons with regard to creativity is even more challenging, given the complexity involved in this multifaceted concept. For example, the focus could be on the creative individual, the creative process, product or outcome, the environment (sometimes called “press”) in which creativity occurs (and which in its psychological sense includes other people)—or indeed any combination of these. Traditionally, Western cultures have been regarded as placing greater emphasis on an end product, whereas Eastern cultures have been seen as putting greater emphasis on the creative process (see [Lubart, 2010](#)).

Then there is a question of the *level* of creativity under consideration, for instance, whether high-level creativity is the appropriate focus of attention or whether everyday creativity merits recognition. Terminology can also be problematic. For example, in psychology, those working in different psychological traditions may use different terminology to denote the same creative phenomena (see for instance [Fryer, 1989](#)).

Furthermore, in many languages, there is more than one word to denote creativity. For example, according to Kwasniewska ([Fryer and Fryer-Bolingbroke, 2011](#)) in Polish, *twórczość* is used in an artistic context to describe the sum of one’s creative work rather than one’s potential. It is most often used to describe the fact that a person creates something. It is more important that something comes to life than the fact that this thing is unique or novel. For scientists, however, *twórczość* always needs to be both novel and valuable. *Kreatywność* is used in business contexts to describe one’s intellectual potential rather than one’s work, as a feature of character. So in Polish you would say that a person, but not a picture, is *kreatywny*. The term *kreatywny* often means that someone is innovative and produces novel ideas, although these are not necessarily valuable.

[Fryer’s 1989](#) investigation into teachers’ views on creativity also revealed significant intergroup differences in perceptions of creativity that indicated that everyone does not mean the same thing when referring to creativity and researchers need to be aware of this ([Fryer, 1989, 1996; Fryer and Collings, 1991](#)). Although it has been widely accepted that it is useful to adopt some objective criteria for defining creativity, even these pose challenges for a cross-cultural approach. For example, the four creativity criteria (novelty, transformation, condensation, and appropriateness) identified by [Jackson and Messick \(1965\)](#) have proved invaluable for creativity researchers, but these do not always translate well across cultures.

[☆] *Change History:* November 2019. Marilyn Fryer & Caroline Fryer updated the text throughout the article.

This article is an update of M. Fryer, C. Fryer-Bolingbroke, Cross-Cultural Differences in Creativity, Editor(s): Mark A. Runco, Steven R. Pritzker, Encyclopedia of Creativity (Second Edition), Academic Press, 2011, Pages 326–334.

Novelty

In the West, novelty in some form is normally regarded as a necessary condition of creativity, and it is the impact that a novel product or process has, which determines whether or not it is seen as creative. To assess whether a creative product could be regarded as novel in a global sense would require a high level of specialist knowledge. On the other hand, it can be argued that a creative product is novel for the person who made it (for example, a child doing something for the first time, with no knowledge of what has gone before). Societies also vary in terms of the amount of novelty they will tolerate. To illustrate this, [Cropley \(2004\)](#) gave the example of the sentencing of Galileo in 1633 for supporting the Copernican position that the earth orbits the sun.

According to Sharma Sen and Sharma ([Fryer and Fryer-Bolingbroke, 2011](#)), in India, among the traditional rural–semiurban population, creativity is perceived as the skill to create artifacts, which they believe need not be original every time. However, whether such artifacts can legitimately be called creative is a matter for debate and depends on who is qualified to judge. Sharma Sen and Sharma pointed out that, among the urban educated, the Western notion of creativity (implying novelty, originality) is accepted. Whether or not Western influence is desirable is open to debate—for instance, does this result in a loss of cultural diversity?

Transformation

In Western cultures, there is an assumption that a highly creative new product demonstrates a radical shift in approach. However, this may not be the case in some Eastern cultures. For instance, [Lubart \(2010\)](#) described how Li compared Chinese ink-brush painting and modern Western painting:

Chinese ink brush painting was viewed as a “vertical” domain in which some elements are essential in each work, and certain aspects can be modified ... In contrast, modern Western painting is a horizontal domain with novelty allowed, supposedly, on all aspects. Thus, novelty can occur “in all directions” in modern Western painting, but only in certain directions in Chinese ink brush paintings.

Condensation

[Jackson and Messick \(1965\)](#) described condensation as the capacity to allow continued contemplation without exhausting meanings and implications. This criterion seems more appropriate for great works of art, music, or literature, rather than, for example, an invention. Perhaps this is the most culturally transferable of Jackson and Messick’s four criteria.

Appropriateness

This concerns the extent to which a product is appropriate to its context. [Paletz and Peng \(2008\)](#) used an implicit theory approach to explore the validity of appropriateness and novelty among over 400 students from Japan, China, and the United States. To do this, they used repeated measures scenarios of cooking and textbook products. They concluded that appropriateness was more important for Americans and Japanese for evaluations of creativity and desire for products. They also concluded that while novelty was important for them all, the Chinese were more swayed than the Americans by novelty with regard to their degree of desire for the product.

The Social Context of Creativity

The fact that creativity does not exist in a vacuum, but in a social context has long been stressed both by Stein ([Fryer, 2004](#)) and [Cropley \(2004\)](#). Cropley (an Australian who spent much of his career working overseas) argued that society is ambivalent about creativity and that two opposing forces are operating: conserving forces which resist change and innovating forces that favor it. Importantly he noted that not all conservation is reactionary or undesirable and not all innovation is beneficial. Furthermore, creativity can be achieved through evolutionary as well as revolutionary change.
